Name: Prof. Nathaniel Howard

ABSTRACT

Multicollinearity and autocorrelation problems pose a major challenge to the Ordinary Least Squares (OLS) estimate. The purpose of the study is to make a comparative analysis of different regularized and robust regression methods to determine the regression method that best addresses multicollinearity and autocorrelation problems in a linear model. The regularized and robust regression methods used in the study include Ridge Regression (RR), Lasso Regression, Two-Stage Ridge Regression (TR), Two-Stage Lasso Regression (TLasso), Quantile Regression (QR), Ridge Quantile Regression (RQR), Lasso Quantile Regression (LQR), Two-Stage Ridge Quantile Regression (TRQR) and Two-Stage Lasso Quantile Regression (TLQR), as remedies to OLS estimate. The data used for the study consists of simulated and two real datasets with multicollinearity and autocorrelation issues. The Mean Squared Error as the main performance criterion as well as other statistical values (such as regression coefficients, R-squared, adjusted R-squared, Root Mean Squared Error) were used for comparing the performances of the regression methods. The results indicate that the TLQR method with 0.5 quantile level is suitable for handling multicollinearity and autocorrelation problems with many predictor variables. The TR method performs better with few predictor variables. Another important observation is the effect of sample sizes on the regression methods. To effectively build a good model, one should aim at choosing the appropriate samples and predictors with corresponding right regression method for data studies which include possible multicollinearity and autocorrelation issues.

ACKNOWLEDGEMENTS

The success of this thesis has been possible largely because of the dedication and commitment of the contributors and their efforts are hereby acknowledged. I wish to express my profound gratitude to my supervisor, Prof Nathaniel Howard for his time, patience, guidance, encouragement and contribution that has made this thesis a success. I am also grateful to Dr David K. Mensah, for his various contributions to the success of this thesis. I would like to acknowledge all lecturers of the Department of Statistics, University of Cape Coast for their support throughout the MPhil studies. I also appreciate the support and encouragement from all my colleagues and the non-academic staff of the Department of Statistics of the University. Finally, to all who has contributed to this thesis in diverse ways, I say thank you and may the good God richly reward your efforts.

CHAPTER ONE

INTRODUCTION

In this introductory chapter, the challenges multicollinearity and autocorrelation pose to linear models has been specified in the background to the study. It is on this background that this study attempts to present different regularized and robust regression methods in handling multicollinearity and autocorrelation problems in linear models. The study also puts into perspective other studies done in the area using other regression methods.

Background to the Study

The Ordinary Least Squares (OLS) estimator is the most widely used estimator for estimating the parameters of a regression model. The OLS estimate has some very interesting statistical properties that have made it one of the most powerful and commonly used estimators of regression models, under certain assumptions. When there is no violation of the classical linear regression model assumptions, OLS outperforms other estimators in parameter estimation. (Lukman, Osowole, & Ayinde, 2015). According to the Gauss-Markov theorem, the OLS estimate has the least mean squared error of all linear estimators with no bias (Greene, 2003; Hastie, Tibshirani & Friedman, 2009). The OLS estimator with $\mathrm{E}(\mathbf{e}) = 0$ and $\mathrm{var}(\mathbf{e}) = \sigma^2 \mathbf{I}_n$ is considered the Best Linear Unbiased Estimator (BLUE), according to the Gauss-Markov theorem. This indicates that, of all the linear estimators, OLS will have the smallest variance, guaranteeing that the regression estimates are unbiased.

There is a biased estimator that has a lower mean squared error. A little bias for a larger reduction in variance would then be traded for by the biased estimator. Therefore, methods that shrinks or sets to zero some of the regression

coefficients of the least squares may produce a biased estimate. These penalized estimation methods were developed to reduce estimate variance and thus improve prediction by means of introducing a slight bias into model estimation (Hastie, Tibshirani, & Friedman, 2009). Recently, much emphasis has been placed on biased estimation of regression coefficients in a linear model. This development is due to the inability of the OLS to provide accurate estimates when the matrix of predictor variables is ill-conditioned. If the predictors are orthogonal, the OLS estimator is optimal among the class of linear unbiased estimators. However, if the regression model contains highly correlated predictors, multicollinearity occurs.

Multicollinearity is one ill-conditioned problem in linear regression models. The term "multicollinearity" was first used in literature by Frisch (1934) on the topic; "statistical confluence analysis by means of complete regression systems". Multicollinearity is "a statistical phenomenon that happens when two or more predictor variables in a regression model are highly correlated" (Corlett, 1990; Jensen & Ramirez, 2013; Johnson, Reimer, & Rothrock, 1973). Multicollinearity may cause issues with the computation of OLS estimations. The multicollinearity issue in fact bedevils the whole subject of linear regression, and is surprisingly a common phenomenon. It is one reason why the multicollinearity problem is 'an art as well as a science' (Bingham & Fry, 2010). The greater a predictor variable's correlation with the other predictor variables in a model, the greater its variance. An estimator will therefore have lower variance when there is a greater variation in the model's predictor variables.

The nature of multicollinearity can be classified into perfect (or exact) and imperfect (or approximate). Multicollinearity is used to mean the presence of a

"perfect" or exact linear relationship between some or all predictor variables in a regression model. It is, however used more broadly to include both the case of perfect multicollinearity and the case where the predictor variables are inter-correlated but not perfectly correlated (Gujarati & Porter, 2009). As a result, its degree must be determined, varying from no collinearity to perfect collinearity. Perfect multicollinearity is an extreme and rare case that occurs when two or more predictor variables in a regression model are linearly dependent. The case of a perfect linear relationship among predictors is a serious failure of the model's assumptions, not of the data. When the predictor variables have an exact relationship, the OLS estimates of the regression coefficients are indeterminate, and the standard error of the estimates becomes infinite. In the case of perfect multicollinearity, the matrix $\mathbf{X}^T\mathbf{X}$ and matrix $\mathbf{X}$ do not have full rank. Consequently, the inverse matrix $(\mathbf{X}^T\mathbf{X})^{-1}$ cannot be computed, therefore $\hat{\boldsymbol{\beta}}_{OLS} = \left(\mathbf{X}^T\mathbf{X}\right)^{-1}\mathbf{X}^T\mathbf{y}$ cannot be solved, and the OLS estimator has no unique solution (Flexeder, 2010; Hashem, 2014).

The most common situation of multicollinearity is when the variables are highly, but not perfectly correlated. In this scenario, regression estimates are determinate but possess large standard error implying that the coefficients cannot be estimated with great precision. When high degree of multicollinearity exists, the matrix $\mathbf{X}^T\mathbf{X}$ is quasi-singular (ill-conditioned). Thus, $\mathbf{X}$ is of full rank and matrix $\mathbf{X}^T\mathbf{X}$ is regular and has a unique solution. However, due to highly correlated predictors in the model, the determinant $\left|\mathbf{X}^T\mathbf{X}\right|$ reaches a value near zero and the computed OLS estimate possesses a very large variance, $var(\hat{\boldsymbol{\beta}}_{OLS}) = \sigma^2(\mathbf{X}^T\mathbf{X})^{-1}$ (Flexeder, 2010; Giacalone, Panarello, & Mattera,

2018). If the determinant defined by $\left|\mathbf{X}^T\mathbf{X}\right| = \prod_{i=1}^{n} \lambda_i$ gives one or more small eigenvalues when multicollinearity is high but imperfect, the distance from OLS vector $(\hat{\boldsymbol{\beta}}_{OLS})$ to true parameter $(\boldsymbol{\beta})$ will tend to be large, that is, $\|\boldsymbol{\beta}_{OLS}\| \geq \|\boldsymbol{\beta}_{true}\|$ (Hoerl & Kennard, 1970).

The presence of multicollinearity would misleadingly inflate in an excessive amount the standard error, and the regression coefficients may not appear significant. Despite OLS having the very desirable property of being BLUE under the usual model conditions, OLS estimators can have extremely large mean squared errors in the presence of multicollinearity. Many approaches have been developed in detecting as well as solving problems associated with multicollinearity in regression analysis. When multicollinearity is detected, the simplest approach is to drop the variable(s) or the problematic variables from the model (Demaris, 2004; Giacalone, Panarello, & Mattera, 2018; Weisberg, 2005), increase the number of observations or add new data (Demaris, 2004; Gujarati & Porter, 2009), combine time series and cross-sectional data (Gujarati & Porter, 2009), incorporate variables into a scale (Demaris, 2004), utilize variable transformation (Demaris, 2004; Gujarati & Porter, 2009), and apply centering for multicollinearity caused by cross-product terms (Demaris, 2004). However, there are times when none of these solutions are satisfactory (Demaris, 2004).

Several methods in literature have been proposed to handle multicollinearity problem in regression analysis. For instance, Stein (1956) proposed stein estimator; Least Absolute Shrinkage and Selection Operator (LASSO) developed by Tibshirani (1996); Hoerl and Kennard (1970) developed Ridge regression; Zou and Hastie (2005) designed the Elastic net, by combining the

L_1-penalty (Lasso) and the L_2-penalty (Ridge); Massy (1965) suggested Principal Component Regression estimator (PCR); and Wold (1966) introduced Partial Least Squares to handle multicollinearity problem.

The autocorrelation problem is a violation of the error term assumption of independence in the classical linear regression model. When the Gauss-Markov assumption of uncorrelated error terms is violated, autocorrelation occurs. The correlation between elements of a time-ordered series of observations, as in time series data, is characterized as autocorrelation (Gujarati, 2003). In the context of regression, the classical linear regression model implies that autocorrelation does not occur in the errors. When this assumption fails, we have an autocorrelation problem. Violation of the no autocorrelation assumption on error terms, will lead to inefficiency of the OLS estimates. The variance of the regression coefficients estimated will be biased and inconsistent, and it will be larger than the variances calculated by other methods. As a result, among all linear unbiased estimators, the OLS estimators will no longer have the least variance. If the errors are interrelated, OLS may underestimate the standard error of the coefficients. Standard errors that are underestimated can make predictors appear significant when indeed they are not. This leads to wrong standard errors for the regression coefficient estimates, therefore, testing of hypotheses is no longer valid. The *F*-statistic and *t*-statistic will tend to be higher and therefore, may not be valid (Damoder, 2006). Furthermore, the OLS estimates are not asymptotic if the error terms are correlated. In other words, estimated β s are not asymptotically efficient (Greene, 2003; Gujarati, 2003).

Several corrective procedures based on variable transformations have been proposed, to correct for autocorrelation. They are, the use of Generalized Least Squares (GLS) or Feasible Generalized Least Square (FGLS) techniques such as the Prais-Winsten estimator, Cochrane-Orcutt estimator, Hildreth and Lu estimator, Durbin estimator, Thornton estimator, Theil's estimator, Maximum Likelihood estimator and Maximum Likelihood Grid estimator (Cochrane & Orcutt, 1949; Hildreth & Lu, 1960; Paris & Winstein, 1954; Thornton, 1982; Theil, 1971; Beach & Mackinnon, 1978).

Inevitably, both problems (autocorrelation and multicollinearity) can coexist in a linear regression model (Hussein, 2009), hence proven in literature (Ayinde *et al.*, 2015; Bayhan & Bayhan, 1998; Lukman *et al.*, 2015; Ozkale & Tugba, 2015; Trenkler 1984; Tugba, 2020; Tugba & Ozkale, 2019). For instance, the generalized ridge estimator (Trenkler, 1984), the feasible generalized ridge estimators (Bello *et al*., 2017) and the combination of the generalized least squares and the ridge regression (Hussein & Zari, 2012) to mitigate both problems. The design of the feasible generalized ridge (FGR) estimator to correct for both problems (Eledum & Zahri, 2013). The combination of the Liu estimator and the feasible generalized least squares to develop the feasible generalized Liu (FGL) estimator (Dawoud & Kaçıranlar, 2016).

Quantile regression (QR) analysis is used to overcome unsatisfactory assumptions, such as autocorrelation, no multicollinearity, normality assumptions and variance homogeneity (Yanuar, Yozza, Firdawati, Rahmi, & Zetra, 2019). QR estimates the conditional median (or other quantiles) of response variable, whereas OLS estimate the response variable's conditional

mean across predictor variables. When estimating the various quantiles of a conditional distribution, QR is used. QR models outperform linear regression (mean regression) models in terms of robustness to outliers (Reed, 2011). Regularization (for instance, Ridge and Lasso) in quantile regression has been proven to improve prediction accuracy (Bager, 2018; Li & Zhu, 2008; Li, Lin, & Xi, 2010; Suhail, Chand, & Kibria, 2020; Wu & Liu, 2009). As a result, it is vital to explore more regularized and robust regression methods in handling multicollinearity and autocorrelation problems, hence, the need for this study.

Statement of the Problem

The general linear regression model makes the fundamental assumption that there is no correlation (or multicollinearity) between the predictors and that there is no autocorrelation. When assumption of no correlation (or multicollinearity) between predictor variables is violated, OLS estimates become unstable, have large variances, and may have an incorrect sign (Greene, 2012). Furthermore, when the multicollinearity degree gets higher, the OLS estimate becomes imprecise, the model may have insignificant tests, wider confidence intervals, parameters with less interpretability, and the OLS being the BLUE does not hold anymore. The existence of multicollinearity makes estimating the unique effects of distinct variables in the regression model unfeasible.

Again, when the assumption of no autocorrelation is not met, the OLS estimator, although linear and unbiased no longer have minimum variance among all linear unbiased estimators (Gujarati, 2003). The OLS estimates are consistent and unbiased, even with correlated error terms. The problem is the efficiency of these estimates. Forecasts based on OLS in the presence of

autocorrelation will be unbiased, but inefficient due to inefficient estimates of the regression parameters. The estimated variance of the regression parameters will be biased, resulting in an erroneous test of hypotheses. Due to the fact that $cov(\mathbf{e}_t, \mathbf{e}_s) \neq 0$, the BLUE that minimizes variance will not be the same as OLS estimate. Therefore, OLS estimator is not BLUE and hence is inefficient.

The traditional approaches of dealing with multicollinearity problems in regression analysis have some limitations. When dropping problematic variables from a model, it can be difficult to decide which variable(s) to be dropped from the model. However, the dropped variable(s) may reduce model's predictive power, and sometimes the variable(s) may be too significant to leave out of the analysis. It may also lead to a problem of bad-specification, specifically, specification bias or specification error, where in some case there is no assurance of whether the model will exhibit less multicollinearity (Gujarati & Porter, 2009). The approach of increasing the number of observations may help in reducing the sampling variance of estimates, but economic constraints may also not allow increasing the number of observations by collecting additional data. Also, the addition of new data may not match with the earlier data collected and may be unusual. Increasing the sample size, according to Chatelain and Ralf (2014), may result in a false inference of strongly correlated classical suppressors. The technique of merging time series and cross-sectional data may create interpretation problems of regression models (Gujarati & Porter, 2009).

Our interest is to squeeze out maximum information from the multicollinearity and autocorrelation data at our disposal and this has motivated the study of the performance of some regression methods. This study, therefore,

suggests a suitable alternative to the least squares estimator to mitigate both problems. One approach in addressing the problem is to apply regularization to robust regression methods. It is therefore relevant to explore from a different perspective by combining a robust regression method and regularized methods. We therefore make a comparative study to evaluate performances of different regularized and robust regression methods when multicollinearity and autocorrelation problems are present under conditions of different degrees of autocorrelation, different sample size, different number of predictors and different multicollinearity levels.

Purpose of the Study

The main purpose of the study is to make a comparative analysis of different regularized and robust regression methods when autocorrelation and multicollinearity problems are present in a dataset. The aim is to determine if regularized and robust regression methods reduce total model error and which of the methods under consideration is the most effective in handling autocorrelation and multicollinearity problems.

Research Objectives

Specifically, we seek to:

1. Compare the performance of Ridge regression, Lasso regression, Two-Stage Ridge regression and Two-Stage Lasso regression methods as remedies to OLS method in the presence of autocorrelation and multicollinearity problems.
2. Develop the Two-Stage Ridge Quantile regression and Two-Stage Lasso Quantile regression methods.

3. Compare the performance of Two-Stage Ridge Quantile regression and Two-Stage Lasso Quantile regression with Ridge Quantile regression and Lasso Quantile regression on multicollinear and autocorrelated data. Objectives (1) and (3) are carried out under conditions of different number of predictor variables, different sample size, different multicollinearity levels and different degrees of autocorrelation.

Significance

The findings of the study are expected to make a significant contribution to the development of suitable regularized and robust regression methods for handling autocorrelation and multicollinearity problems in linear model. The findings of the study will help us to understand the degree of multicollinearity for which OLS should be preferred over regularized regression and robust regression methods.

The study will suggest the best estimation method that gives the least mean squared error under multicollinearity and autocorrelation conditions for a given number of predictor variables, at different sample sizes, for different multicollinearity levels and different autocorrelation degrees. This will further help to know the effect of sample size and samples to be collected from a highly homogeneous population with multicollinearity problem when a particular regression method is to be used.

The study will be helpful to future researchers by providing them views about the best regression estimator to handle multicollinearity and autocorrelation problems.

Delimitations

This study focuses on solving autocorrelation and multicollinearity problems in linear regression analysis using regularized and robust regression methods for real and simulated data. The study focused on the use of regularized and robust methods on a simulated dataset to compare their performance at different multicollinearity levels, different degrees of autocorrelation, different number of predictor variables and different sample sizes.

The difficulty in getting real data with different degrees of multicollinearity, different degrees of autocorrelation, different number of predictor variables and different sample sizes resulted in the used of data simulations to help us compare the performance of the regularized and robust regression methods.

Firstly, comparison is made between the regularized regression methods as single estimators to evaluate their performance on multicollinearity and autocorrelation dataset using MSE criteria. Secondly, comparison is made between the combinations of different regularized regression methods and quantile regression method as combined estimators, to know which one performs better on multicollinearity and autocorrelation dataset.

Limitations

The study focused on multicollinearity and autocorrelation problems regardless of other issues, such as outliers and heteroscedasticity problems. Again, since this is a simulation study, data has been generated in an attempt to enable for generalization to practical circumstances. Also, with regards to Quantile Regression method used in combination to regularized methods, there are other possible members of the robust regression method that may be used to construct the title of combined regularized and robust regression methods.

Organisation of the Thesis

The thesis is organized into five chapters. Chapter One, the introduction of the study highlights the background, statement of the problem, purpose of the study, research objectives, significance, delimitations and limitations of the study. Chapter Two presents the literature review. It covers both theoretical frameworks and empirical reviews related to the concepts under study. Chapter Three deals with the research methodology employed to accomplish the study. The chapter discussed the mathematical and statistical methods and procedures used in the data analysis. Chapter Four covers the results and discussions of the study. The final chapter, Chapter Five, covers the summary, conclusions and recommendations, as well as suggestions for further studies.

Chapter Summary

This chapter described multicollinearity and autocorrelation, and highlighted the implications of multicollinearity and autocorrelation on the regression coefficient of OLS estimators. When multicollinearity and autocorrelation are present, the performance of the OLS estimate was found to be unsatisfactory. The traditional approaches of handling autocorrelation and multicollinearity problems in regression model have some limitations, and there are times when none of these approaches are satisfactory. We give the main motivation that has been captured in the problem statement together with the research objectives. Therefore, this study introduces regularized and robust regression methods to address the problems of autocorrelation and multicollinearity. We concluded the chapter by presenting an outline for the thesis.

CHAPTER TWO

LITERATURE REVIEW

Introduction

This chapter discusses the challenges multicollinearity and autocorrelation pose to linear models. The chapter delves into some works done by other researchers and authors in addressing multicollinearity and autocorrelation problems. The chapter is structured as follows; overview of OLS, nature, source and effect of multicollinearity and autocorrelation, test for multicollinearity and autocorrelation, solutions to models with multicollinearity and autocorrelation, regularization and regularized regression methods, regularized estimators in robust regression methods, and literature on addressing multicollinearity and autocorrelation problems.

Overview of Ordinary Least Squares

The OLS estimate is considered as Best Linear Unbiased Estimator (BLUE). It is useful for investigating the linear relationships between variables of interest. OLS regression is based on assumptions, and when those assumptions hold true, the OLS regression produces the best estimates. When the assumptions are met, the OLS generates better estimates than any other linear model estimating methods, according to the Gauss-Markov theorem (Greene, 2003; Hastie, Tibshirani, & Friedman, 2009). One of the most important goals of regression analysis is to explain the relationship between predictors and response variable.

The effectiveness of regression analysis is highly dependent on the structure of correlations between predictive variables. If the predictors are orthogonal, OLS estimator is optimal among the class of linear unbiased estimators.

Multicollinearity develops when the regression model contains highly correlated predictors. Again, when the uncorrelated error terms assumption is violated, autocorrelation occurs.

Autocorrelation leads to inefficiency of the OLS estimates. Consider the multiple linear regression model

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{e}$$

where $\boldsymbol{\beta}$ is a $(p+1)\times 1$ vector of unknown parameters and $\boldsymbol{\varepsilon}$ is an $n\times 1$ vector of random errors with $\mathrm{E}(\mathbf{e}) = 0$ and $\mathrm{var}(\mathbf{e}) = \sigma^2\mathbf{I}_n$. The response variable is arranged in the $n\times 1$ vector $\mathbf{y}$ and the data for the predictor variables are in the $n\times(p+1)$ matrix $\mathbf{X}$. Multicollinearity violates the assumption that the design matrix $\mathbf{X}$ is given the full rank, rendering OLS estimation unfeasible. When a model does not have full rank, inverse of matrix $\mathbf{X}$ cannot be determined.

Nature of Multicollinearity and Autocorrelation

Multicollinearity develops when a linear relationship exists between two or more than two variables; in contrast to multicollinearity, collinearity can refer to either the general scenario of a linear dependence among predictors or a linear relationship between only two predictors. The nature of multicollinearity can be classified into perfect (or exact) and imperfect (or near) multicollinearity. If the predictor variables in a model exhibit perfect correlation, statistical software will fail to fit the model and produce an error notice. Statistical software, on the other hand, can fit OLS regression models with imperfect but strong relationships between predictors. However, correlations can cause issues if they are strong enough.

In the case of perfect multicollinearity, the matrix $\mathbf{X}$ and matrix $\mathbf{X}^T\mathbf{X}$ lack full rank. Consequently, the inverse matrix $(\mathbf{X}^T\mathbf{X})^{-1}$ cannot be computed, therefore $\hat{\boldsymbol{\beta}}_{OLS} = \left(\mathbf{X}^T\mathbf{X}\right)^{-1}\mathbf{X}^T\mathbf{y}$ cannot be solved and the OLS estimator has no unique solution (Flexeder, 2010; Hashem, 2014). In the case of imperfect multicollinearity, the matrix $\mathbf{X}^T\mathbf{X}$ and matrix $\mathbf{X}$ have full rank, however, it is not far from being rank-deficient. The inverse of matrix $(\mathbf{X}^T\mathbf{X})^{-1}$ can be computed, therefore $\hat{\boldsymbol{\beta}}_{OLS} = \left(\mathbf{X}^T\mathbf{X}\right)^{-1}\mathbf{X}^T\mathbf{y}$ can be solved and the OLS estimator has a unique solution. However, the computed OLS estimator possesses a very large variance. A high multicollinearity level can either result in an erroneous inversion or prohibit the statistical software from completing a matrix inversion while calculating the regression coefficients.

The importance of multicollinearity stems from the fact that, estimates of OLS regression coefficients may vary unpredictably in response to slight changes in predictors. As a result, in linear regression analysis, the ability to detect multicollinearity is critical. Such detection entails two interconnected steps: first determining the existence of a multicollinearity problem, and then determining its severity or strength.

The classical model assumes that the error term associated with any observation is unaffected by any other observation's error term. Autocorrelation occurs when an important assumption that all error terms for all observations are independent of each other, is violated during an OLS regression analysis. It can cause issues in conventional analyses that assume observation independence such as OLS regression. Because it refers to a lack of independence between values, autocorrelation is problematic for most statistical

tests. First-order autocorrelation, which can be positive or negative, is the most common type of autocorrelation.

Sources and Effects of Multicollinearity and Autocorrelation

There are two basic sources of multicollinearity, that is, Structural and Data-based multicollinearity. When a researcher creates new predictor variables or a model term using other terms, structural multicollinearity occurs. In other words, it is a result of the model specified by the researcher rather than being present in the data itself. It results from the use of predictor variables that are powers or linear combinations of another set of variables. For instance, if term X is squared to model curvature by researcher, there is clearly a relationship between term X^2 and X. Multicollinearity may increase with any combination of the original variables if the sampling subspace for the predictor variables is narrow. Data-based multicollinearity is inherent in the data rather than results of researcher's model. Data-based multicollinearity is caused by poorly designed experiments, observational data issues, or non-manipulable data collection methods, and is more common in observational experiments. It also occurs in data collection methods when the data is assembled from a small subspace of the predictor variables. This is multicollinearity caused by poor sampling methodology.

Researchers face issues when predictors are highly, but not perfectly, correlated. One issue with data multicollinearity might be that small variations in the dataset generate large swings in estimations of parameters. Multicollinearity also results in coefficients having very high standard errors. Due to multicollinearity, coefficients may result in implausible magnitudes or "wrong" sign. The confidence interval for coefficient estimators will be wider

due to multicollinearity (Mela & Kopalle, 2002). Increased standard error of the coefficients may result in some predictor variables being insignificant (Gujarati & Porter, 2009), whereas these same coefficients could have been found to be significant with lower standard errors and no multicollinearity (Greene, 2012).

Although multicollinearity reduces the model's power to identify statistically significant predictor variables and also makes it difficult to interpret coefficient of regression estimates, it has no effect on predictions, precision of predictions, or goodness-of-fit statistics (Montgomery, Peck, & Vining, 2012).

There are several sources of autocorrelation. Autocorrelation can occur whenever there is some ordering of sampling units. The effect of removing some variables is another source of autocorrelation. Mis-specifying the type of relationship can introduce autocorrelation into the data. If there are exponential or log terms in the model, the model's linearity is put into question, and this may cause autocorrelation in the data. Carryover of effect is a significant source of autocorrelation, at least in part. Autocorrelation can also be caused by systematic measurement errors.

Ordinary regression suffers when the independent errors assumption is violated. The OLS estimates of the regression coefficients are still consistent and unbiased when the error terms are autocorrelated, but the minimum variance property is not satisfied. R-squared will be overestimated in the majority of cases and hypothesis testing is no longer valid. The traditional F and t significance tests are no longer valid, and if used, are likely to produce significantly misleading results with respect to the statistical significance of the computed regression parameters. Another effect is the OLS estimates are not asymptotic when the error terms are autocorrelated. Because the OLS estimates

will be inefficient, they will no longer be BLUE (Damoder, 2006; Greene, 2003; Gujarati, 2003).

Test for Multicollinearity

A variety of methods can be used to detect multicollinearity. Some of the most common methods are discussed below.

Correlation Matrix

A correlation matrix is a table that illustrates the correlation coefficients among variables. Multicollinearity can be determined by inspecting a predictor variable correlation matrix for high correlation.

Variance Inflation Factor (VIF)

The VIF measures how much a given predictor's linear correlation with the other predictors raises the variance of its coefficient estimate in comparison to the baseline case of no correlation, and is defined as

$$VIF_i = \frac{1}{1-R_i^2}$$

where R_i^2 is the coefficient of determination of a regression of predictor i on all the other predictors. A VIF of 5 or 10 and above implies a multicollinearity issue (O'Brien, 2007). The denominator $1-R_i^2$ is known as tolerance.

Eigenvalues, Condition Indexes and Condition Number

For eigenvalues, multicollinearity is indicated by smaller eigenvalues of $\mathbf{X}^T\mathbf{X}$ or its related correlation matrix. One or more small eigenvalues that are smaller than other eigenvalues indicate that the variables have near-linear dependencies.

The condition indexes (CI) of the $\mathbf{X}^T\mathbf{X}$ matrix is defined as,

$$CI_i = \frac{\max(\lambda_i)}{\lambda_i},\ i = 1,2,\cdots p$$

Where λ_i are eigenvalues. The number of near-linear dependences in $\mathbf{X}^T\mathbf{X}$ is determined by the number of "large" condition indexes. Condition indexes ranging from 5 to 10 shows weak dependencies, whereas condition indexes ranging from 30 to 100 shows moderate to strong dependencies (Belsley, 1991).

The condition number (CN) of the $\mathbf{X}^T\mathbf{X}$ matrix is defined as,

$$k = \frac{\max(\lambda_i)}{\min(\lambda_i)},\ i = 1,2,\cdots p$$

Where $\max(\lambda_i)$ and $\min(\lambda_i)$ are maximal and minimal eigenvalues respectively, and λ_i are the eigenvalues. The condition number is most commonly used to determine whether the inversion of $\mathbf{X}^T\mathbf{X}$ may result in numerical issues. From no serious, moderate to strong, and severe multicollinearity problems, respectively, are associated with condition numbers less than 100, between 100 and 900, and greater than 900 (Belsley, 1991).

Farrar χ^2

Farrar χ^2 is a Chi-square test for detecting the degree of multicollinearity across the entire set of predictors and is defined as $\chi^2 = -\left(n - 1 - \frac{1}{6}(2p+5)\right)\log\left(\left|\mathbf{X}^T\mathbf{X}\right|\right) \sim \chi^2\left(-\frac{1}{2}p(p-1)\right)$.

The multicollinearity exists among predictors if $\chi^2 > \chi^2\left(-\frac{1}{2}p(p-1)\right)$ (Farrar & Glauber, 1967).

Klein's rule

According to Klein's rule, multicollinearity is a major issue if the degree of inter-correlation is greater than the overall multiple correlation degree. That is, $R_i^2 > R_y^2$, where R_i^2 is from a regression of predictor variable i on all of the others and R_y^2 is from a regression of response variable y on all predictor variables (Klein, 1962).

Corrected VIF (CVIF)

The corrected VIF (CVIF) as a new multicollinearity index was defined by Curto and Pinto (2011):

$$CVIF_i = VIF_i \times \frac{1-R^2}{1-R_o^2}$$

Where $R_o^2 = R_{yx1}^2 + R_{yx2}^2 + \cdots + R_{yxp}^2$, and R_{yx1}^2, R_{yx2}^2, R_{yx3}^2, $\cdots$, R_{yxp}^2 are the coefficient of correlation between **y** and x_i with $i = 1,2,\cdots p$. The corrected VIF measure is used to evaluate the influence of the predictor variables correlation on the variance of the OLS estimators. Collinearity exists if $CVIF_i \geq 10$.

Test for Autocorrelation

There are several methods for detecting autocorrelation, the most common of which are the graphical method and the Durbin-Watson test.

Graphical Method

The estimated residuals are plotted against time in a graph. The residual plot's clustering effect is used to determine the presence of autocorrelation. The residuals should be randomly distributed around the zero line, if the data are independent. However, if a discernible pattern emerges (especially one that is

cyclical), dependency is most likely present, or if successive residuals tend to cluster on one side or the other of the zero line, it is a pictorial sign that autocorrelation exists.

Durbin-Watson Test

The Durbin-Watson test only takes into account first-order autocorrelation. Durbin-Watson can test the hypothesis:

$H_o : \rho = 0$ (The errors are not correlated)

$H_A : \rho \neq 0$ (The errors are correlated)

The Durbin-Watson test statistic is defined as follows;

$$D = \frac{\sum_{t=2}^{n}(e_t - e_{t-1})^2}{\sum_{t=1}^{n} e_t^2}$$

where $e_t = y_t - \hat{y}_t$ are the residuals from the OLS fit. The Durbin-Watson tests produces statistic ranging from 0 to 4, where values ranging from 0 to 2 indicate positive autocorrelation, 2 indicate zero autocorrelation, and values ranging from 2 to 4 indicate negative autocorrelation.

Solutions to models with Multicollinearity and Autocorrelation

Multicollinearity issues can be addressed by removing a redundant or problematic variables from the model, increasing the number of observations or adding new data, transforming or recoding multicollinear variables, incorporating variables into scale or centering if multicollinearity arises from cross-product terms, and using regularization methods (Demaris, 2004; Giacalone, Panarello, & Mattera, 2018; Gujarati & Porter, 2009). When multicollinearity problem exists in a regression model, it is critical to determine

which predictor variables are causing the problem, and the simplest approach is to remove the model variables that are problematic. Also, if a variable is redundant, dropping it is simply correcting a specification error. Also, to simply correct a specification error, remove redundant variables from the model. Stepwise regression procedures are formal methods that accomplish essentially the same thing.

Increasing the sample size improves an estimator's precision and reduces the negative effects of multicollinearity. Even if the variance of the OLS estimates is inflated by high correlation among predictors, the variance tends to decrease; additionally, a larger sample size reduces over-fitting and tends to reduce R-squared. Multicollinearity problems are reduced by re-specifying the model, such as by combining multicollinear variables. The approach is effective in controlling multicollinearity when it was caused by experiment design or model specification rather than a sampling problem.

Regularization methods such as Ridge and Lasso, are frequently employed to "solve" the problem of multicollinearity. Regularization methods add restriction information on the value of β or some combination of regression coefficients. These restrictions can be applied to mitigate the effects of multicollinearity. Principal Component Analysis is used in Principal Component Regression (PCR) to convert the original variables into a new set of uncorrelated linear variables. Principal component analysis is also employed in Partial Least Squares (PLS) regression to generate a set of uncorrelated components to include in the model.

Autocorrelation issues can first be addressed by investigating the absence of any other key predictor variable. The variables are then transformed when such

predictor variable cannot be identified to eliminate autocorrelation from the model. The dataset is transformed so that the resulting modified model's error term conforms to the OLS assumption of no autocorrelation. One popular technique is to simply proceed with a first difference model. Redesigning the variables with a Generalized Least Squares (GLS) or Feasible Generalized Least Square (FGLS) methods such as the Prais-Winsten estimator, Cochrane-Orcutt estimator to address autocorrelation problems (Cochrane & Orcutt, 1949; Paris & Winstein, 1954).

Regularization and Regularized Regression Methods

Generally, the OLS estimate performs poorly when there is multicollinearity. However, the linear model suffers from high variance while having a low bias. This is where a popular Goldilocks solution called "regularization" and sometimes called "shrinkage" come to rescue (Berk, 2020; Hastie, Tibshirani, & Friedman, 2009). They are approaches to addressing the bias-variance trade-off in the context of statistical learning. Shrinkage, on the other hand, is regarded as a subset of regularization in which the loss function of ordinary linear regression is modified to incorporate a complexity penalty (Berk, 2020; Hastie, Tibshirani, & Friedman, 2009).

Regularization is essential in modern data analysis. This allows for a reduction in variance at the expense of some bias, ultimately lowering the total error of the model. The process regularizes regression coefficients and, as a result, the fitted values. Conventional regression methods cannot handle data with more predictors (p) than observations (n) (i.e. $p >> n$). Some of the coefficients are reduced to zeros using these methods. When there are a large number of parameters, regularization is also required to avoid over-fitting.

Regularized regression methods for linear regression have evolved to outperform the shortcomings of OLS regression in terms of prediction precision. Regularizing the model is a way of reducing undesirable effects or structural parameters where weights are constrained. Regularization methods are also used as a variable selection method for determining the most important variables in a model. They are used to control the regression coefficients, which can reduce variance and sample error and thus solve the multicollinearity problem.

In general, two main techniques are employed in improving the OLS estimation procedure. One method focuses on identifying biased estimators with lower MSE than OLS estimators. Lasso regression and Ridge regression are examples. The second technique, on the other hand, deals directly with the predictor variables' dependency nature, such as PLS regression and PCR. There have been studies comparing regularized models (Gnat, 2020; Melkumova & Shatskikh, 2017).

According to a study conducted by Gnat (2020), regularization enhances outcomes and allows for reduced average absolute percentage errors. In the study, two regularization methods (Ridge regression and Lasso regression) were used in assessing their impact on errors. The study also confirms the effectiveness of regularization in removing the problem of model overfitting or multicollinearity. According to studies from literature, the less data you have, the more beneficial it is to use regularization (Gnat, 2020).

Regularized estimators in Robust Regression Methods

According to Giacalone *et al*. (2018), some robust estimators are preferred in the remedy to problems of multicollinearity, because it handles both multicollinearity and outliers simultaneously. Since OLS is highly sensitive to

outliers, robust regression methods are intended to address some of the shortcomings of OLS estimate when outliers are present. Addressing these issues, there have been several robust regression estimators developed, such as Huber's M-estimators (Huber, 1964), S-estimators (Rousseeuw & Yohai, 1984), Least Median of Squares estimators and Least Trimmed Squares estimators (Rousseeuw, 1984), MM-estimators (Yohai, 1987), Robust and Efficient Weighted Least Squares estimators (Gervini & Yohai, 2002), τ-estimators (Yohai & Zamar, 1988), and Quantile regression methods (Koenker & Bassett, 1978). Other methods, such as the Bisquare Ridge LTS estimators (BRLTS) (Pati *et al.*, 2016) and Ridge Least Absolute Value (RLAV) (Pfaffenberger & Dielman, 1985), have combined regularized methods and robust regression methods, which should be preferred, according to Giacalone *et al*. (2018).

The majority of techniques in literature are centered on mean regression, and outliers are particularly sensitive to mean-centered regressions (Aguinis, Gottfredson, & Joo, 2013). Regularization (for example, Ridge and Lasso) in Quantile regression (QR) has been shown to improve prediction accuracy (Bager, 2018; Li & Zhu, 2008; Li, Lin, & Xi, 2010; Suhail, Chand, & Kibria, 2020; Wu & Liu, 2009). Koenker (2004) is the first to use regularization in QR, where the Lasso penalty on random effects was applied in a mixed-effect QR model to shrink individual effects towards a common value. Bayesian technique by incorporating an L_2-penalty into the check function of standard QR to shrinking random effects to a common value was also proposed by Yuan and Yin (2010). Yu, Alkenani, and Alhamzawi (2012) proposed adaptive Lasso quantile regression and a flexible Bayesian Lasso approach. The proposed

methods were compared to Lasso quantile regression (LQR), Flexible Bayesian quantile regression (FBQR), and QR methods. They found that the proposed methods outperform the alternative methods.

Zaikarina, Djuraidah, and Wigena (2016) researched on "Lasso and ridge quantile regression using cross validation to estimate extreme rainfall". They used quantile regression with Lasso and ridge regularizations and modified percentile cross validation. Local monthly rainfall and precipitation data from the "Global circulation model (GCM)" were used in the study at Indramayu, Indonesia, from 1981 to 2013. They found that the modified percentile method criteria for selecting optimal Lasso and ridge coefficients provide good prediction on both Lasso and ridge quantile regressions. Their results showed that quantile regression with ridge regularization performed better than Lasso. Adlouni, Salaou, and St-Hilaire (2018) considered five penalties (Lasso, Ridge, SCAD0, SCAD1, SCAD2, Ridge and Lasso) combined with quantile regression in Bayesian framework. They found that the Lasso for quantile estimation had the best performance according to the Relative Mean-Error (RME) and Relative Mean Bias (RMB) criterion, particularly when dealing with heavily distributed errors.

Related Works on addressing Multicollinearity Problems

In a study conducted by Irfan, Javed, and Raza (2013), Ordinary Least Squares (OLS), Principal Component Regression (PCR), Partial Least Squares (PLS) and Ridge Regression (RR) methods were compared to address the multicollinearity problem on Pakistani GDP data from 1973 to 2011. On the basis of the Cross Validation Parameter (CVP), Root Mean Square Error Cross Validation (RMSECV), RMSE and R-Squared, the PLS regression approach

was discovered to produce superior data findings than the other regression methods. In a study performed by El-Fallah and El-Salam (2014), PLS regression, PCR and RR methods were compared in their study on multicollinearity. The effectiveness of these three regression methods was assessed using Monte Carlo simulation study. The MSE criterion was used to assess the efficiency of the three regression methods. The simulated data used consist of p = 2, 4, 6 and 25 predictor variables for n = 20, 30, 40, 50 and 60 sample sizes. Their findings show that the RR performs best with small number of predictors (p = 2), while the PLS performs best with moderate number of predictors (p = 4, 6) and high (p = 25). They also found that, PLS and RR outperformed PCR in all cases.

Firinguetti, Kibria, and Araya (2017) carried out a simulation study to compare Ridge regression and PLS to OLS. The findings of their study revealed that both the RR and PLS methods result in significant reductions in MSE over the OLS method. They also found that as multicollinearity increases, neither method appears to be preferred over the other. However, with large error variance, the RR performs better, and with model that contains more variables, the PLS method works best. Goktas and Akkus (2020) compared the performance of RR, PLS and PCR methods based on MSE values in simulated research. Simulations were run for six different levels of multicollinearity (0.0, 0.3, 0.5, 0.7, 0.9 and 0.99), six different sample sizes (30, 50, 100, 200, 500 and 1000) and three different number of variables (4, 7 and 9). The simulation was run 10,000 times with three different number of predictors (4, 7 and 9). Their results show that the number of predictors, sample size and level of multicollinearity all have an effect on each prediction method. Based on the

obtained findings, it was observed that when there is severe multicollinearity among predictors, the PCR method produces significantly superior estimates.

Herawati, Nisa, Setiawan, Nusyirwan, and Tiryono (2018) used data simulation to assess the performances of OLS, RR, PCR and Lasso methods in addressing severe multicollinearity problems. The data simulated show severe multicollinearity between predictors ($\rho = 0.99$), five different number of predictor variables ($p = 4, 6, 8, 10, 20$) and five different sample sizes ($n = 25, 50, 75, 100, 200$) with 100 iterations using the R package. The Akaike Information Criterion (AIC) and Average Mean Square Errors (AMSE) criterion were employed to assess the methods performances. They found that the RR and PCR methods can overcome severe multicollinearity problems. Overall, they concluded that PCR is the best method for estimating regression coefficients on data with severe multicollinearity.

Adepoju and Ojo (2018) proposed a Bayesian estimation method for linear regression models with the use of informative priors (conjugate) in existence of multicollinearity. The Bayesian method was compared to that of the OLS method using a simulation study, with Confidence Intervals (CI), Standard Error (SE), and MSE as criterion for evaluation and comparison. The simulated data were generated with two different multicollinearity degrees (0.80 and 0.95) and sample sizes were varied between 30, 200 and 300 with three predictor variables. According to the simulation results, the Bayesian method with an informative prior outperformed the OLS method. As a result, they recommended the Bayesian estimation method for dealing with multicollinearity, especially when there is sufficient prior information and the degree of multicollinearity is high. Another study on Bayesian method with the

application of informative prior was carried out by Jaya, Tantular, and Andriyana (2019). They then used the MSE, Bias and power of the test criterion to reveal that the Bayesian method outperformed the RR method. They also showed that, in multicollinear regression analysis, the Bayesian method can be used to efficiently address hypothesis testing.

Suhail, Chand, and Kibria (2020) developed a new type of ridge estimator based on quantile and compared its performance with other RR and OLS methods in a simulation study. Their results showed that the proposed method outperforms alternative approaches, particularly when error variance and multicollinearity are high. They also showed that increasing the sample size and a large number of predictor variables results in a corresponding reduction in estimator MSE values. Davino, Romano, and Vistocco (2022) researched on "handling multicollinearity in quantile regression through the use of principal component regression". They applied PCR principles to quantile regression by proposing Quantile Principal Component Regression (QPCR). The study used both simulated and empirical data to investigate collinearity's effect on QR. The simulation study employed three predictors and 100 observations with varying degrees of correlation. For each design grid, they ran 1000 simulations. Their results reveal that as collinearity rises, standard errors in OLS increase, while those in QR increase more. However, when PCR is used, the results' stability in the various scenarios is confirmed. The study's main findings are the importance of collinearity in QR and the application of PCR as a viable remedy.

Jegede, Lukman, Ayinde, and Odeniyi (2022) combined the Jackknife Kibria-Lukman (JKL) estimator and the M-estimator to form the Robust Jackknife Kibria-Lukman (RJKL) estimator to address outliers and

multicollinearity. In the simulation, multicollinearity degrees were set to 0.70, 0.80, 0.90, and 0.99, and sample sizes were varied between 50, 100, 200, and 250 with three different values of σ (1, 5, and 10). They included an outlier of 10%, 20%, and 30% in each sample size considered in the simulation study. The simulation was repeated 2000 times, each time with a different predictor variable (p = 3 and p = 7). They also used the Hussein data from Eledum and Alkhaklifa (2012) study for data analysis. The performances of ridge, M-estimator, ridge M-estimator, Kibria-Lukman (KL) estimator, robust KL estimator, JKL estimator, and RJKL estimator were investigated. The RJKL estimator performed well in both the simulation research and the real-life data analysis. Based on the MSE criterion of each regression estimator, they concluded that the RJKL estimator outperforms the other existing estimators.

According to studies in the literature, researchers have devised a combined-estimator technique to handling multicollinearity problem in regression analysis that outperforms the single-estimator approach. For instance, the $r-k$ class estimator which combines ridge regression (RR) and PCR (Baye & Parker, 1984), the Liu estimator which combines the idea of RR and stein estimator (Liu, 1993), the $r-d$ class of estimator which combines the PCR and Liu estimator (Kaciranlar & Sakallioglu, 2001), a new two-parameter estimator which combines the OLS, RR, Liu, and contraction estimators in special cases (Ozkale & Kaciranlar, 2007), and another new two-parameter estimator by combining the OLS, RR, and the Liu estimators in a different manner (Yang & Chang, 2010).

Principal component two-parameter (PCTP) estimator is proposed by Chang and Yang (2012), which combines PCR and another two-parameter estimator

developed by Yang and Chang (2010). Ozkale (2012) developed a general class of estimator called the $r-(k,d)$ class estimator, and the developed estimator was a combination of a number of regression estimators (OLS, RR, contraction, PCR, Liu, $r-d$ and $r-k$ class estimators) into a single-estimator. The superiority of the $r-(k,d)$ class estimator was obtained over the OLS, RR, PCR, $r-d$ class, $r-k$ class, $\hat{\beta}(k,d)$, Liu and contraction estimators under the scalar MSE criterion. The concept of transitioning to a combined-estimator technique from a single-estimator technique is a gradual process aimed at resolving multicollinearity issues in regression analysis models (Ayinde, Alabi, & Nwosu, 2021).

Related Works on addressing Autocorrelation Problems

Beach and MacKinnon (1978) indicated that estimating the regression parameters with first-order autocorrelation, the widely used Cochrane-Orcutt and Hildreth-Lu procedures typically ignore the first observation. As a result, they proposed the maximum likelihood estimator (MLE), takes into consideration the first observation. They explained that the maximum likelihood procedure functions like the Cochrane-Orcutt procedure but seems to be more computationally efficient. They presented Monte Carlo results and concluded that the maximum likelihood procedure is theoretically superior to the conventional ones.

Kramer (1980) investigated the "finite sample efficiency of ordinary least squares in the linear regression model with autocorrelated errors". The OLS, Prais-Winsten, and Durbin estimators were investigated. In 100 or 500 Durbin and Prais-Winsten sample runs, efficiency is calculated analytically for OLS.

The obtained results strongly demonstrated that the Durbin and Prais-Winsten methods outperform OLS.

Tanizaki (2003) compares the Maximum Likelihood estimator (MLE) to the Bayes estimator (BE) for estimating models with first-order autocorrelated errors. The Metropolis-Hastings algorithm and Gibbs sampler algorithm are employed in the Bayes estimator. The study used Monte Carlo studies to compare BE to MLE, with the standard error (SE), arithmetic average (AVE), and RMSE as comparison criterion. The Bayes estimator was found to be more efficient and less biased than the maximum likelihood estimator in the AVE, SE, and RMSE criteria. The results showed the superiority of BE over MLE because BE values for both the variance of the error term and autocorrelation coefficient are closer to true values than MLE values. Overall, the results show that the Bayes estimator outperformed the maximum likelihood estimator.

Desviona and Yanuar (2020) conducted a study on "simulation study of autocorrelated error using Bayesian quantile regression". They compared the ability of the classical QR and Bayesian quantile regression methods to estimate linear models with autocorrelated error problems. The posterior distribution for the Bayesian quantile regression was estimated using Gibbs sampler algorithm by applying Markov Chain Monte Carlo method. The simulated data employed in the study consisted of two predictor variables each generated from N (0,1) with 150 observations. For parameter estimation, the method with the smallest confidence interval and least absolute value of bias is considered best. The Bayesian quantile method, according to the findings, produces lower confidence intervals and absolute bias values than the QR method. They concluded that the Bayesian quantile regression method outperforms the QR method.

Literature on addressing Autocorrelation and Multicollinearity Problems

Eledum and Alkhalifa (2012) developed the generalized two stages ridge regression (GTR) by combining the generalized ridge regression (GRR) with the two-stage procedure (TS) for dealing with linear models that suffer from multicollinearity and autocorrelation. They derived some statistical properties of the GTR biased estimator. Real data example was employed to achieve the study purpose, with the data representing "the product in the manufacturing sector, capital commodities, imported intermediate and imported raw materials in Iraq from 1960 to 1990". The GTR regression estimator was compared to the OLS, RR, GRR, two-stage regression, and two-stage ridge regression estimators. They found that the GTR estimator has the smallest MSE and thus outperforms the other regression estimators based on the MSE criterion of each regression estimate.

Eledum and Zahri (2013) introduced a two-stage ridge regression (TR) for autocorrelated errors and multicollinear data. After adjusting it with the RR, they applied the two-stage regression (TS) using a mixed method. They also derived the statistical properties of the TR biased method and use an application example to compare the TR estimator's performance with OLS, TS, and RR estimators. They concluded that the TR estimator is unbiased, with lower MSE, variance, and bias than the RR estimator. Eledum and Awadallah (2021) also researched the two-stage ridge regression method for dealing with autocorrelation and multicollinearity problems in linear models. The TR method's performance is evaluated using Simulation study, with MSE used as a criterion for evaluation. Three different multicollinearity degrees (0.70, 0.80, and 0.99), three different autocorrelation degrees (0.5, 0.7, and 0.99), and four

different sample sizes (10, 30, 70, and 100) were simulated. The simulation was run 10,000 times. The results showed that the TR method outperforms the RR, and the regularization parameter values for the TR are always less than those for the RR.

Ayinde, Lukman, and Arowolo (2015) conducted a study that combined Principal Component estimator with two Feasible Generalized Least Square Estimators (Cochrane-Orcutt and Maximum Likelihood estimators) to handle problems of autocorrelation and multicollinearity in linear models. The following estimators were compared in performance: OLS, ridge, PC1, PC12, ML, MLPC1, MLPC12, MLPC123, CORC, CORCPC1, CORCPC12 and CORCPC123. The MSE of estimators at each multicollinearity level, autocorrelation, and parameter was ranked in Monte Carlo studies. The degrees of multicollinearity were 0.9, 0.95, and 0.99, while the degrees of autocorrelation were 0.7, 0.8, 0.9, 0.95, and 0.99. The simulation was run 1000 times with four different sample sizes (10, 20, 30, and 50). The findings revealed that the MLPC1 estimator is generally the best, despite the fact that PC1 and CORCPC1 compete favorably with it. Furthermore, the MLPC12 and CORCPC12 are often the best with larger sample sizes.

In research conducted by Dawoud and Kaçıranlar (2016), they proposed the Two-Stage Liu (TL) method to address autocorrelation and multicollinearity issues in linear models. The performance of the TL method over the others was investigated using real data example and Monte Carlo simulation studies. Three different multicollinearity degrees (0.70, 0.80, and 0.90), five different autocorrelation degrees (0.1, 0.3, 0.5, 0.7, and 0.99), and two different sample sizes (20 and 60) with six different values of σ (0.1, 0.5, 1, 4, 9, and 20) were

simulated. In their study, they also used the Portland cement data from Woods, Steinour, and Starke (1932). The MSE criterion was employed to evaluate the following methods performances: TL, OLS, RR, TS, TR, Liu, Stein, and Two-Stage Stein (STS). The real data and simulation results revealed that TL method has a lower MSE than the other methods. However, when the σ increases, the STS method produces similar or better results over TL method.

A study conducted by Arowolo, Adewale and Kayode (2016) compared the Two-Stage Principal Component regression (T-PC) and Two-Stage Partial Least Square (T-PLS) when a linear model suffers from problems of autocorrelated error and multicollinearity. The study used a real-life dataset from the publication of World Bank (2015) on Gross Domestic Product (GDP), export, import, government capital formation and foreign direct investment for the year 1981 to 2013. The RMSE and RMSE cross validation was employed as criterion for comparison of methods. They found that T-PLS and T-PC perform similarly; however, T-PLS has a higher predictive power.

Ozbay, Kaçıranlar and Dawoud (2017) proposed Feasible Generalized Restricted Ridge regression (FGRR) method to address autocorrelation and multicollinearity issues in linear models at the same time. They derived some statistical properties of FGRR estimator and used a Monte Carlo simulation to compare FGRR estimator to others using matrix MSE criterion. The simulated data were generated with three different multicollinearity degrees (0.7, 0.8, and 0.9), and the errors were obtained by either an MA (1) process or an AR (1) process, where ρ is considered as -0.8, -0.4, 0.0, 0.4, 0.8 with $p = 4$ and $n = 20$. They used τ to control the true or false restriction, and it is chosen as 1, 1.05, or 1.10 and remains constant throughout the simulation. The simulation was

replicated 5000 times. The performance of the following estimators was compared: RR, Restricted Least Squares (RLS), Feasible Generalized Restricted Least Squares (FGRLS) and FGRR. In comparison to the other estimators, they found that FGRR estimator has lower MSE values and therefore outperforms the other estimators.

Oyewole and Agunbiade (2020) carried out research on "regression techniques in the presence of multicollinearity and autocorrelation phenomena: a Monte Carlo approach". They proposed the generalized least squares-ridge (GLS-R) regression method by combining GLS and ridge regression to deal with autocorrelation and multicollinearity problems. However, because $\boldsymbol{\Omega}$ is unknown, parameter estimates for the biased GLS-R estimator are impossible to obtain in practice. To approximate those parameters, they combined Durbin's two-step method with RR. The study's data was simulated using Monte Carlo. The performances of four different estimation methods were investigated: OLS, Ridge regression, Lasso regression, and the GLS-R method. According to their findings, the GLS-R regression method has the lowest AIC and MSE value of the four methods. As a result, they found that the GLS-R regression method is more predictive and provides the preferred estimator in estimating all of the model's parameters based on the AIC and MSE criterion, and thus it is preferred over the OLS, ridge, and Lasso regression methods.

Zubair and Adenomon (2021a) proposed the two-stage $K-L$ estimator to address autocorrelation and multicollinearity issues in linear regression models. The performance of the two-stage $K-L$ estimator is evaluated using Monte Carlo Simulation, with MSE used as a criterion for evaluation. Autocorrelation and multicollinearity degrees were both set to 0.6, 0.8, and 0.9, and sample sizes

ranged from 25, 50, 100, 250, and 500. The simulated data used included six predictor variables, and the process was repeated 1000 times. The Prais-Winsten, OLS, Cochrane-Orcutt, Restricted Maximum Likelihood estimator (RMLE) and MLE estimators were compared to the two-stage $K-L$ estimator. They found that the two-stage $K-L$ estimator performs similarly to MLE and RMLE under severe collinearity and autocorrelation conditions. They further found that, under moderate collinearity and severe autocorrelation conditions, whatever the sample size, the two-stage $K-L$ estimator outperforms all other estimators and appears to perform better with larger sample sizes. The study suggested that, to avoid erroneous inferences, the multicollinearity level and autocorrelation degree between variables be considered when estimating regression model parameters.

Another study was conducted by Zubair and Adenomon (2021b) on the "robustness test of the two-stage $K-L$ estimator in models with multicollinear regressors and autocorrelated error term". The estimators were applied to two real data sets with autocorrelation and multicollinearity issues (Hussein data and French economy data). The two-stage $K-L$ estimator was compared to the OLS, Prais-Winsten, Cochrane-Orcutt, MLE and RMLE under the MSE and RMSE criterion. The study's findings revealed that two-stage $K-L$ estimator outperforms the other estimators in both applications to real data. The findings from the real data confirm the findings of the simulation study in work of Zubair and Adenomon (2021a), which also found that two-stage $K-L$ estimator is preferred in fitting a linear model with assumptions of multicollinearity and autocorrelation are violated.

Chapter Summary

The literature has revealed the extent to which multicollinearity and autocorrelation problems pose a challenge to OLS regression. The chapter has described the nature and sources of multicollinearity and autocorrelation. The literature is clear on the effect of multicollinearity and autocorrelation on regression models. The chapter identified ways of detecting multicollinearity and autocorrelation in a linear model. The chapter has also reviewed some approaches in handling autocorrelation and multicollinearity problems. The literature established that the traditional approaches of handling autocorrelation and multicollinearity problems in regression model have some limitations, and there are times when none of these approaches are satisfactory.

Regularization is essential in modern data analysis and therefore, regularization methods were introduced as possible methods in addressing multicollinearity issues. It was noted that regularization in quantile regression improve prediction accuracy. Regularized and robust regression methods have clear advantage over the regularized regression methods, because it handles both multicollinearity and outliers simultaneously. The chapter further reviewed literature on addressing multicollinearity and autocorrelation problems. Simulation studies have mainly been used in studying performances of regression methods in addressing multicollinearity and autocorrelation. The results suggest that the degrees of multicollinearity and autocorrelation have effect on performance of regression methods. Furthermore, sample size and number of predictors were found to have effect on MSE values of regression methods.

CHAPTER THREE

RESEARCH METHODOLOGY

Introduction

In this chapter, we review the methods employed in the analysis of the data. The chapter describes the data and regression methods employed in addressing the problems of multicollinearity and autocorrelation. We review the L_1 and L_2 regularization methods employed to correct for multicollinearity and the two-stage method adopted to correct for autocorrelation. We further present the formulation of the regularized and robust regression methods. Applying these regression methods to linear models with multicollinearity and autocorrelation problems, the goal is to find the regression method that best addresses multicollinearity and autocorrelation problems in a dataset.

Linear Regression Model

A linear regression model describes the relationship between one or more predictor variables, $X_1, X_2, \cdots, X_p$, and a response variable, y. The model relating the response, y, to p predictor variables, $x_1, x_2, \cdots, x_p$, is given by

$$y_i = \beta_0 + \beta_1 x_{i1} + \beta_2 x_{i2} + \cdots + \beta_p x_{ip} + e_i .$$

Now for n independent observations of y and associated values of x_i, the model becomes

$$\begin{aligned} y_1 &= \beta_0 + \beta_1 x_{11} + \beta_2 x_{12} + \cdots + \beta_p x_{1p} + e_1` \\ y_2 &= \beta_0 + \beta_1 x_{21} + \beta_2 x_{22} + \cdots + \beta_p x_{2p} + e_2 \\ &\vdots \\ y_n &= \beta_0 + \beta_1 x_{n1} + \beta_2 x_{n2} + \cdots + \beta_p x_{np} + e_n \end{aligned}$$

In matrix form, the system of equations above is written as

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{e} \qquad (1)$$

where,

$$\mathbf{y}=\begin{bmatrix} y_1 \\ y_2 \\ \vdots \\ y_n \end{bmatrix},\ \mathbf{X}=\begin{bmatrix} 1 & x_{11} & x_{12} & \cdots & x_{1p} \\ 1 & x_{12} & x_{22} & \cdots & x_{2p} \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ 1 & x_{n1} & x_{n2} & \cdots & x_{np} \end{bmatrix},\ \boldsymbol{\beta}=\begin{bmatrix} \beta_0 \\ \beta_1 \\ \vdots \\ \beta_p \end{bmatrix} \text{ and } \mathbf{e}=\begin{bmatrix} e_1 \\ e_2 \\ \vdots \\ e_n \end{bmatrix}.$$

When the model errors are normally and independently distributed, the maximum-likelihood estimators for the model parameters in multiple linear regression are also least squares estimators. The normal density function for the errors is

$$f(\boldsymbol{e}_i)=\prod_{i=1}^{n}\frac{1}{\sqrt{2\pi\sigma^2}}\exp\left(-\frac{\boldsymbol{e}_i^2}{2\sigma^2}\right)$$

The likelihood function is the joint density of $e_1, e_2, \ldots, e_n$ or $\prod_{i=1}^{n} f(e_i)$. Therefore, the likelihood function is

$$L(\boldsymbol{e},\beta,\sigma^2)=f(\boldsymbol{e}_i)=\prod_{i=1}^{n}\frac{1}{\sqrt{2\pi\sigma^2}}\exp\left(-\frac{1}{2\sigma^2}\boldsymbol{e}^T\boldsymbol{e}\right).$$

Now since we can write $\boldsymbol{e}=\mathbf{y}-\mathbf{X}\beta$, the likelihood function becomes

$$L(\mathbf{y},\mathbf{X},\beta,\sigma^2)=\frac{1}{(2\pi)^{n/2}\sigma^n}\exp\left(-\frac{1}{2\sigma^2}(\mathbf{y}-\mathbf{X}\beta)^T(\mathbf{y}-\mathbf{X}\beta)\right).$$

According to Stuart (2011), if the assumptions of the error terms are met, that is, the $e_i \sim N(0,\sigma^2\mathbf{I}_n)$, then the least squares estimator is the maximum likelihood estimator for β, maximizing

$$\frac{1}{(2\pi)^{n/2}\sigma^n}\exp\left(-\frac{1}{2\sigma^2}(\mathbf{y}-\mathbf{X}\beta)^T(\mathbf{y}-\mathbf{X}\beta)\right) \qquad (2)$$

over β, which is equivalent to maximizing the logarithm of Equation (2) over β: $\ln L(\mathbf{y},\mathbf{X},\beta,\sigma^2)=-\frac{n}{2}\ln(2\pi)-n\ln(\sigma)-\frac{1}{2\sigma^2}(\mathbf{y}-\mathbf{X}\beta)^T(\mathbf{y}-\mathbf{X}\beta)$.

This corresponds to minimising $(\mathbf{y}-\mathbf{X}\beta)^T(\mathbf{y}-\mathbf{X}\beta)=\sum_{i=1}^{n}\boldsymbol{e}_i^2$ since σ is a constant. Therefore, the minimization of the residual sum of squares $\sum_{i=1}^{n}\boldsymbol{e}_i^2$ is the least squares estimate $\hat{\beta}$. Therefore, the maximum-likelihood estimator of β under normal errors is equivalent to the least squares' estimator $\hat{\beta}=(\mathbf{X}^T\mathbf{X})^{-1}\mathbf{X}^T\mathbf{y}$.

Review of Ordinary Least Squares (OLS)

The OLS method is used to estimate the regression coefficients in that the residual sum of squares is to be minimised.

It minimizes the least squares loss function

$$\|\mathbf{y}-\mathbf{X}\boldsymbol{\beta}\|^2 \tag{3}$$

The least squares estimate aims to minimize the sum of the square residuals as

$$\begin{aligned}\sum_{i=1}^{n}\boldsymbol{e}_i^2 &= \boldsymbol{e}^T\boldsymbol{e}\\ &= (\mathbf{y}-\mathbf{X}\beta)^T(\mathbf{y}-\mathbf{X}\beta)\\ &= \mathbf{y}^T\mathbf{y}-\mathbf{y}^T\mathbf{X}\beta-\beta^T\mathbf{X}^T\mathbf{y}+\beta^T\mathbf{X}^T\mathbf{X}\beta\end{aligned}$$

By minimizing the errors

$$\begin{aligned}\frac{\partial}{\partial\beta}\left(\sum_{i=1}^{n}\boldsymbol{e}_i^2\right) &= \frac{\partial}{\partial\beta}\left(\mathbf{y}^T\mathbf{y}-\mathbf{y}^T\mathbf{X}\beta-\beta^T\mathbf{X}^T\mathbf{y}+\beta^T\mathbf{X}^T\mathbf{X}\beta\right)\\ &= 0-\mathbf{X}^T\mathbf{y}-\mathbf{X}^T\mathbf{y}+2(\mathbf{X}^T\mathbf{X})\beta\\ &= 0-2\mathbf{X}^T\mathbf{y}+2(\mathbf{X}^T\mathbf{X})\beta\end{aligned}$$

Now, the least squares estimator $\hat{\beta}$ is the solution to

$$\mathbf{X}^T\mathbf{X}\hat{\beta}=\mathbf{X}^T\mathbf{y}$$

Therefore, when $\mathbf{X}^T\mathbf{X}$ is non-singular the least squares estimate can be evaluated directly from the data by

$$\hat{\beta} = (\mathbf{X}^T\mathbf{X})^{-1}\mathbf{X}^T\mathbf{y} \quad (4)$$

Linear Model Regularization

Regularization is performed by applying weight constraints on the model. These constraints are implemented in various ways by different algorithms. Ridge and Lasso regression are two forms of regularization used in this study. Model weights in regression models are determined by minimizing the model's residual sum of squares (RSS). The key stage for both methods of regularization is the selection of the regularization parameter, k. For ridge regression, a regularization term equal to $k\sum_{j=1}^{p}\beta_j^2$ is added to RSS loss function of Equation (3). The regularization parameter k controls how much of the model should be regularized. If $k=0$, then Ridge regression is simply an OLS. If k is large, all weights are very close to zero, resulting in a flat line passing through the mean of the data. Setting k is thus an important stage in the creation of a model in order to produce good quality outputs.

The model weights are regularized in the case of Lasso regression by adding an expression $k\sum_{j=1}^{p}|\beta_j|$ to loss function of Equation (3). An important feature of Lasso regularization, is the elimination of the least significant variables from models. Assume we have a large dataset (say, 1000 predictors) and some predictors are correlated. Then, both Ridge and Lasso penalty terms are used. In the Ridge regression method, all 1000 predictors are retained in the model, but their coefficients are shrunk toward zero (but not exactly zero) to retain the model's complexity. In contrast, Lasso regression will reduce some of the coefficients to exactly zero, therefore reducing the model's complexity while

improving its prediction accuracy. As a result, by maintaining only the important variables in the model, the Lasso penalty function naturally achieves the optimal model.

Ridge Regression

According to Hoerl and Kennard (1970), the potential instability in employing OLS estimates could be improved by adding a small constant k to the $\mathbf{X}^T\mathbf{X}$ matrix diagonal entries before taking its inverse. When the predictors are highly correlated, the Ridge regression approach is utilized to improve the estimation of regression parameters. Because of the $\|\boldsymbol{\beta}_{OLS}\| \geq \|\boldsymbol{\beta}_{true}\|$ problem in Equation (4) when the matrix $\mathbf{X}^T\mathbf{X}$ is ill-conditioned, Ridge regression's penalty term is designed in such a way that the length of the parameter vector β is restricted.

The estimates for the Ridge regression parameters are obtained by minimizing the residual sum of squares subject to an L_2-penalty on the coefficients.

$$\hat{\beta}_{Ridge} = \min_{\beta}\left\{\sum_{i=1}^{n}(\mathbf{y}_i - \sum_{j=1}^{p}\mathbf{X}_{ij}\beta_j)^2\right\},\ s.t.\ \sum_{j=1}^{p}\beta_j^2 \leq t,\ t \geq 0 \qquad (5)$$

Equivalently, the following minimization problem defines Ridge regression

$$\hat{\beta}_{Ridge} = \min_{\beta}\left\{\sum_{i=1}^{n}(\mathbf{y}_i - \sum_{j=1}^{p}\mathbf{X}_{ij}\beta_j)^2 + k\sum_{j=1}^{p}\beta_j^2\right\},\ k \geq 0 \qquad (6)$$

where $i = 1, 2, \ldots, n;\quad j = 1, 2, \ldots, p$ and the amount of shrinkage is controlled by the regularization parameter, k. The parameter t in Equation (5) is clearly related to the parameter k in Equation (6). This means that for a given value k, there exists a value t for which the estimation Equations (5) and (6) yield the same result.

Rewriting the Equation (6) in matrix form

$$\hat{\beta}_{Ridge} = \min_{\beta} \|\mathbf{y} - \mathbf{X}\beta\|_2^2 + k\|\beta\|_2^2$$

The function can be restated as

$$\hat{\beta}_{Ridge} = \min_{\beta} \left\{(\mathbf{y} - \mathbf{X}\beta)^T(\mathbf{y} - \mathbf{X}\beta) + k\beta^T\beta\right\}$$

Simplifying gives

$$\hat{\beta}_{Ridge} = \min_{\beta} \left\{\mathbf{y}^T\mathbf{y} - 2\beta^T\mathbf{X}^T\mathbf{y} + \beta^T\mathbf{X}^T\mathbf{X}\beta + k\beta^T\beta\right\}$$

Taking the derivative with respect to β, we obtain

$$\frac{\partial}{\partial\beta}\left(\hat{\beta}_{Ridge}\right) = \mathbf{X}^T\mathbf{X}\beta + \mathbf{X}^T\mathbf{X}\beta - 2\mathbf{X}^T\mathbf{y} + 2k\beta$$

$$= 2\mathbf{X}^T\mathbf{X}\beta - 2\mathbf{X}^T\mathbf{y} + 2k\beta$$

Setting the derivative to zero

$$\frac{\partial}{\partial\beta}\left(\hat{\beta}_{Ridge}\right) = 0 \Rightarrow \mathbf{X}^T\mathbf{X}\beta + k\beta = \mathbf{X}^T\mathbf{y}$$

$$\Rightarrow (\mathbf{X}^T\mathbf{X} + k\mathbf{I}_p)\beta = \mathbf{X}^T\mathbf{y}$$

Therefore, the regularized solution is given as

$$\hat{\beta}_{RR} = (\mathbf{X}^T\mathbf{X} + k\mathbf{I}_p)^{-1}\mathbf{X}^T\mathbf{y} \quad (7)$$

where $\mathbf{I}$ is the $p \times p$ identity matrix. By adding $k\mathbf{I}_p$ to $\mathbf{X}^T\mathbf{X}$, this results in a regular and invertible matrix. For strictly positive k Ridge solution in Equation (7) is well-defined despite multicollinearity or $p >> n$ (van Wieringen, 2021).

The Ridge regression method, in contrast to the OLS estimates, is biased. As a result, this regularization method accepts some bias in order to lower the variance and MSE of the estimates and possibly improve the prediction accuracy. As a result, the goal of Ridge regression is to choose a k that is large enough to overcome the problem of near singularity of the matrix of cross-products but not so huge that it introduces a lot of bias. Ridge regression is very popular for non-orthogonal regression issues due to its ability to obtain descent estimates in the presence of multicollinearity (Duzan & Sharif, 2015).

The way one chooses k is an important aspect of Ridge regression. There are many procedures for determining the biasing parameter (k) value. The procedures are classified as either subjective (such as ridge trace, VIF trace, *df* trace, plotting of variance, bias, and MSE) or objective (such as cross-validation, generalized cross-validation, *m*-scale, Information criteria – Bayesian Information Criterion (BIC), AIC) methods. Many different techniques for estimating k have been suggested or proposed by various researchers. To mention a few notable ones, there are: K_{HKB} (Hoerl & Kennard, 1970), K_{LW} (Lawless & Wang, 1976), K_{TH} (Thisted, 1976), K_{DS} (Dwividi & Shrivastava, 1978), K_{AM} (Kibria, 2003), K_{KD} (Dorugade & Kashid, 2010), $K_{4(AD)}$ (Dorugade, 2014). The common ways of doing this is to use the ridge trace graphical method introduced by Hoerl and Kennard (1970), generalized cross-validation and cross-validation method. We used the generalized cross-validation and cross-validation methods in determining the parameter (k).

Lasso Regression

The Lasso is another regularization method which imposes an L_1-penalty on the regression coefficients. The Lasso minimizes the residual sum of squares subject to the sum of the absolute value of the coefficients being less than a constant.

The Lasso estimate $\hat{\beta}$ is defined by

$$\hat{\beta}_{Lasso} = \min_{\beta}\left\{\sum_{i=1}^{n}(\mathbf{y}_i - \sum_{j=1}^{p}\mathbf{X}_{ij}\beta_j)^2\right\},\ s.t.\ \sum_{j=1}^{p}|\beta| \le t,\ t \ge 0 \qquad (8)$$

An equivalent form of the Lasso is

$$\hat{\beta}_{Lasso} = \min_{\beta}\left\{\sum_{i=1}^{n}(\mathbf{y}_i - \sum_{j=1}^{p}\mathbf{X}_{ij}\beta_j)^2 + k\sum_{j=1}^{p}|\beta|\right\},\ k \ge 0 \qquad (9)$$

where $i = 1, 2, \ldots, n$; $j = 1, 2, \ldots, p$ and k is the regularization parameter.

In matrix form

$$\hat{\beta}_{Lasso} = \min_{\beta} \|\mathbf{y} - \mathbf{X}\beta\|_2^2 + k\|\beta\|_1 \quad (10)$$

Tibshirani (1996) defines $t \geq 0$ (or k) as a regularized parameter that can be chosen using generalized cross-validation or cross-validation. There is a choice of k for every choice of t that produces the same result.

The Lasso estimation is a convex optimization issue that can be addressed using a quadratic programming algorithm for a given k. Therefore, solving Equation (9) does not provide a closed form expression. When the regularization parameter k is set to a high value, the Lasso solution is usually sparse as a result of the L_1-penalty. Lasso regression has the same bias penalizing effects, variance rewarding effects, and shrinking capabilities as Ridge regression. However, as k increases, more and more coefficients in Lasso regression will be identically zero (Hastie *et al.*, 2009). Lasso regression can be suitable in handling models with high degree of multicollinearity.

Two-Stage Regression Method

When error terms have autocorrelation, the OLS estimate is still unbiased, but it is no longer a minimal variance estimate, making it inefficient. Variable transformation is one method for addressing estimates in linear autocorrelation models. This study looks at the first-order autoregressive structure AR (1). To deal with autocorrelation, we employed a two-stage method. The two-stage method is used to correct for autocorrelation and the regularized method to correct for multicollinearity.

We used the two-stage procedure outlined below.

1. Obtain an estimate of ρ using the OLS residuals. The estimate of ρ is obtained by

$$\rho = \frac{\sum_{i=2}^{n} e_i e_{i-1}}{\sum_{i=1}^{n} e_i^2}$$

2. The ρ obtained from the OLS was used to transform the data.
3. Two-stage estimator $\hat{\beta}_{TS}$ is obtained by applying OLS to the transformed data. The Durbin-Watson test is then used to test whether error terms for the transformed model are uncorrelated.
4. The regularized and robust regression methods was finally applied to the autocorrelation-free transformed data.

Various transformation approaches have been proposed by different authors. There are those who employ the $\mathbf{P}^*$ matrix and those who employ the $\mathbf{P}$ matrix of transformation. The $\mathbf{P}$ transformation matrix is derived from the AR (1) model for the error term, whereas the $\mathbf{P}^*$ transformation matrix uses a lag definition and loses the first observation. The sole difference between $\mathbf{P}^*$ matrix and $\mathbf{P}$ matrix of transformation is how the first observation is handled. The $\mathbf{P}$ transformation matrix keeps the first observation. The $\mathbf{P}$ transformation matrix is obtained by inserting a new first row with $\sqrt{1-\rho^2}$ in the first position and zero in the other positions in the transformation matrix. It has been shown that with large sample size, the difference between the use of the $\mathbf{P}^*$ matrix and $\mathbf{P}$ matrix is minimal, but with small sample size, the difference is significant (Olaomi, 2008). These approaches are categorized into those that utilize $\mathbf{P}^*$ matrix for transformation, for instance the Hildreth and Lu (HILU) and

Cochrane-Orcutt (CORC) methods, and those that use $\mathbf{P}$ matrix for transformation, for instance the Prais-Winstein method (Olaomi, 2008). We therefore adopted the $\mathbf{P}$ transformation matrix.

The $\mathbf{P}$ transformation matrix is given by

$$\mathbf{P}_{n\times n} = \begin{bmatrix} \sqrt{1-\rho^2} & 0 & 0 & \cdots & 0 \\ -\rho & 1 & 0 & \cdots & 0 \\ 0 & -\rho & 1 & \cdots & 0 \\ \vdots & \vdots & \vdots & \cdots & \vdots \\ 0 & 0 & 0 & \cdots & 1 \end{bmatrix}$$

We consider the linear regression model in Equation (1), that is, $\mathbf{y} = \mathbf{X\beta} + \mathbf{e}$. Pre-multiplying both sides of Equation (1) by the $\mathbf{P}$ transformation matrix, we get an equivalent linear model

$$\mathbf{Py} = \mathbf{PX\beta} + \mathbf{Pe} \tag{11}$$

Let $\mathbf{y}^* = \mathbf{Py}$, $\mathbf{X}^* = \mathbf{PX}$ and $\mathbf{e}^* = \mathbf{Pe}$, then $\mathrm{E}(\mathbf{e}^*) = 0$ and $\mathrm{cov}(\mathbf{e}^*) = \sigma^2\mathbf{I}_n$.

The transformation model is given by

$$\mathbf{y}^* = \mathbf{X}^*\boldsymbol{\beta} + \mathbf{e}^* \tag{12}$$

Model (12) satisfies the error assumption $e^* \sim N(0, \sigma^2\mathbf{I}_n)$.

Therefore, the least squares estimate for the Model (12), which is called the Two-stage is

$$\hat{\beta}_{TS} = (\mathbf{X}^{*T}\mathbf{X}^*)^{-1}\mathbf{X}^{*T}\mathbf{y}^* \tag{13}$$

where $\mathbf{y}^* = \mathbf{Py} = \begin{bmatrix} \sqrt{1-\rho^2} & 0 & 0 & \cdots & 0 \\ -\rho & 1 & 0 & \cdots & 0 \\ 0 & -\rho & 1 & \cdots & 0 \\ \vdots & \vdots & \vdots & \cdots & \vdots \\ 0 & 0 & 0 & \cdots & 1 \end{bmatrix} \begin{bmatrix} y_1 \\ y_2 \\ y_3 \\ \vdots \\ y_n \end{bmatrix}$

$$\mathbf{X}^{*} = \mathbf{PX} = \begin{bmatrix} \sqrt{1-\rho^2} & 0 & 0 & \cdots & 0 \\ -\rho & 1 & 0 & \cdots & 0 \\ 0 & -\rho & 1 & \cdots & 0 \\ \vdots & \vdots & \vdots & \cdots & \vdots \\ 0 & 0 & 0 & \cdots & 1 \end{bmatrix} \begin{bmatrix} 1 & X_{11} & X_{12} & \cdots & X_{1k} \\ 1 & X_{21} & X_{22} & \cdots & X_{2k} \\ 1 & X_{31} & X_{32} & \cdots & X_{3k} \\ \vdots & \vdots & \vdots & \cdots & \vdots \\ 1 & X_{n1} & X_{n2} & \cdots & X_{nk} \end{bmatrix}, \; k = p-1$$

The matrix $\mathbf{P}$ can be specified such that $\mathbf{P}\Omega\mathbf{P}^{T} = \mathbf{I}$, and Ω must be positive definite such that $\mathbf{P}^{T}\mathbf{P} = \Omega^{-1}$. Then the OLS estimate of the transformed variable $\mathbf{PX}$ and $\mathbf{Py}$ in Equation (11) have all of the optimal OLS properties, and the usual inferences could be true.

Now, $\mathbf{X}^{*T}\mathbf{X}^{*} = \mathbf{X}^{T}\mathbf{P}^{T}\mathbf{PX} = \mathbf{X}^{T}\Omega^{-1}\mathbf{X}$ and $\mathbf{X}^{*T}\mathbf{y}^{*} = \mathbf{X}^{T}\mathbf{P}^{T}\mathbf{Py} = \mathbf{X}^{T}\Omega^{-1}\mathbf{y}$

where Ω^{-1} is given by

$$\Omega^{-1} = \frac{1}{1-\rho^2}\begin{bmatrix} 1 & -\rho & 0 & \cdots & 0 & 0 \\ -\rho & 1+\rho^2 & -\rho & \cdots & 0 & 0 \\ 0 & -\rho & 1+\rho^2 & \cdots & 0 & 0 \\ \vdots & \vdots & \vdots & \cdots & \vdots & \vdots \\ 0 & 0 & 0 & \cdots & 1+\rho^2 & -\rho \\ 0 & 0 & 0 & \cdots & -\rho & 1 \end{bmatrix}$$

After obtaining Ω^{-1}, Two-stage is given by $\hat{\beta}_{TS} = (\mathbf{X}^{T}\Omega^{-1}\mathbf{X})^{-1}\mathbf{X}^{T}\Omega^{-1}\mathbf{y}$

We can find $\hat{\Omega}^{-1}$ after estimating ρ, then the Two-stage can be given by

$$\hat{\beta}_{TS} = (\mathbf{X}^{T}\hat{\Omega}^{-1}\mathbf{X})^{-1}\mathbf{X}^{T}\hat{\Omega}^{-1}\mathbf{y} \qquad (14)$$

Now, to correct for multicollinearity, the regularized regression methods are needed. Because the rank of $\mathbf{X}^{*}$ is equal to the rank of $\mathbf{X}$, the multicollinearity in the datasets still affects the Two-stage method. The regularized methods will be required to handle the multicollinearity problem.

Two-Stage Ridge Regression

The two-stage process used to alter the data is now applied to Ridge regression to produce the Two-stage Ridge regression (TR) method. We

replaced $\mathbf{y}$ and $\mathbf{X}$ in Equation (6) by $\mathbf{y}^*$ and $\mathbf{X}^*$, respectively. The solution of the coefficients can be written as

$$\hat{\beta}_{TR} = \min_{\beta} \left\{ \sum_{i=1}^{n} (\mathbf{y}_i^* - \sum_{j=1}^{p} \mathbf{X}_{ij}^* \beta_j)^2 + k \sum_{j=1}^{p} \beta_j^2 \right\}, \; k \geq 0 \tag{15}$$

where $i = 1, 2, \ldots, n$; $j = 1, 2, \ldots, p$ and k is the regularization parameter.

In matrix form

$$\hat{\beta}_{TR} = \min_{\beta} \left\| \mathbf{y}^* - \mathbf{X}^* \beta \right\|_2^2 + k \left\| \beta \right\|_2^2$$

Solving Equation (15) has closed form solution, and the rank of $\mathbf{X}^*$ is equal to the rank of $\mathbf{X}$. Therefore, regularized solution is given by

$$\hat{\beta}_{TR} = (\mathbf{X}^{*T} \mathbf{X}^* + k\mathbf{I}_p)^{-1} \mathbf{X}^{*T} \mathbf{y}^* \tag{16}$$

Following Equations (7) and (14), is the Two-stage Ridge regression proposed by Eledum and Zahri (2013)

$$\hat{\beta}_{TR} = (\mathbf{X}^T \hat{\Omega}^{-1} \mathbf{X} + k\mathbf{I}_p)^{-1} \mathbf{X}^T \hat{\Omega}^{-1} \mathbf{y} \tag{17}$$

Two-Stage Lasso Regression

The two-stage procedure which was used to arrive at the transformed data is now applied to Lasso regression to get the Two-stage Lasso regression (TLasso) method. The complete Lasso cost function is convex and non-differentiable. We replaced $\mathbf{y}$ and $\mathbf{X}$ in Equation (9) by $\mathbf{y}^*$ and $\mathbf{X}^*$, respectively. The solution of the coefficients can be written as

$$\hat{\beta}_{TLasso} = \min_{\beta} \left\{ \sum_{i=1}^{n} (\mathbf{y}_i^* - \sum_{j=1}^{p} \mathbf{X}_{ij}^* \beta_j)^2 + k \sum_{j=1}^{p} |\beta| \right\}, \; k \geq 0 \tag{18}$$

where $i = 1, 2, \ldots, n$; $j = 1, 2, \ldots, p$ and k is the regularization parameter.

In matrix form

$$\hat{\beta}_{TLasso} = \min_{\beta} \left\| \mathbf{y}^* - \mathbf{X}^* \beta \right\|_2^2 + k \left\| \beta \right\|_1$$

Instead of running the Lasso on $\mathbf{y}$ vector of response variable and $\mathbf{X}$ matrix of predictors, we therefore run it on $\mathbf{y}^*$ vector of response variable and $\mathbf{X}^*$ matrix of predictors.

Quantile Regression Method

The Quantile regression (QR) method is widely used to describe the distribution of a response variable given a set of predictor variables. QR, as introduced by Koenker and Bassett (1978), is an extension of classical least squares estimate of conditional mean models to the estimation of an ensemble of models for different conditional quantile functions when the conditions of linear regression are not met. QR allows estimating the entire distribution of the response variable's conditional quantiles. The QR estimates are more robust against outliers in response variables, which is one advantage of QR over OLS estimate. However, the QR extends beyond this advantage and is useful when dealing with conditional quantile functions. In contrast to traditional linear regression, QR does not make any assumptions about the error distribution or assume homogeneous residual variance. In this regard, it is a more adaptable technique than traditional linear regression. When all of the assumptions of the conventional linear regression model are met, QR should produce the same results as the traditional model (Tareghian & Rasmussen, 2013).

A typical QR model is formulated as

$$Q_{\tau}(\mathbf{y} \mid \mathbf{X}) = \mathbf{X}^T \boldsymbol{\beta}_{\tau} \tag{19}$$

where $Q_{\tau}(\cdot \mid \cdot)$ is the conditional quantile function for the τth conditional quantile with $0 < \tau < 1$, τ determines the quantile level, $\mathbf{X}$ is a vector of

predictor variables and $\boldsymbol{\beta}_\tau$ is a vector of parameters related to the τth QR. QR provides separate models for each conditional quantile τ of interest.

Regression coefficients β_τ can be estimated by

$$\hat{\beta}_\tau = \min_{\beta_\tau} \sum_{i=1}^{n} \rho_\tau(\mathbf{y}_i - \mathbf{X}_i^T \boldsymbol{\beta}_\tau) \tag{20}$$

where $\rho_\tau(\cdot)$ is the check function defined by

$$\rho_\tau(y) = \left[(1-\tau)\mathrm{I}(y<0) + \tau \mathrm{I}(y>0)\right]|y|$$

A weighted sum of absolute deviations is used as the check function, where a τ weight is used for the positive deviations and a $(1-\tau)$ weight is assigned to the negative deviations. As a result, QR estimates for Equation (20) can be formulated as

$$\hat{\beta}_\tau = \min_{\beta_\tau} \sum_{y_i < \mathbf{X}_i^T \beta_\tau} (1-\tau)\left|\mathbf{y}_i - \mathbf{X}_i^T \boldsymbol{\beta}_\tau\right| + \sum_{y_i \geq \mathbf{X}_i^T \beta_\tau} \tau \left|\mathbf{y}_i - \mathbf{X}_i^T \boldsymbol{\beta}_\tau\right|$$

QR allows the vector $\hat{\beta}_\tau$ to variate on different τ, the median case ($\tau = 0.5$) being equivalent to minimize the sum of absolute values of the residuals. We employed 0.25, 0.5 and 0.75 quantile levels in the analysis of the QR models.

Regularized and Quantile Regression Methods

The Ridge type and Lasso type penalties have been proposed in the literature to improve the prediction accuracy and interpretability of statistical models in both regularization and variable selection (Hoerl & Kennard, 1970; Tibshirani, 1996; Wang, Li, & Jiang, 2007). The presence of multicollinearity causes large variance, which leads to poor inference and prediction. As a solution to the multicollinearity problem, QR with the Ridge penalty has been proposed (Kibria, 2003). QR with Ridge and Lasso regularization is developed by a QR model using Ridge and Lasso coefficients. We therefore employed QR with

Ridge and Lasso regularization to develop QR models to study their performances on multicollinearity and autocorrelation datasets.

Ridge Quantile Regression Method

The Ridge Quantile Regression (RQR) use the ridge coefficients to build the QR model. The RQR is achieved by adding L_2-penalty to the quantile loss function.

The RQR estimate β is given by

$$\hat{\beta}_{RQR} = \min_{\beta}\left\{\sum_{i=1}^{n}\rho_{\tau}(\mathbf{y}_i - \mathbf{X}_i^T\beta_{\tau}) + k\sum_{j=1}^{p}(\beta_j)^2\right\},\ k>0 \tag{21}$$

where $i=1,2,\ldots,n;\quad j=1,2,\ldots,p$ and k is the ridge parameter.

Lasso Quantile Regression Method

Li and Zhu (2008) introduced Lasso Quantile Regression (LQR) for simultaneous estimation and variable selection in QR models. The L_1-penalty is added to the quantile loss function to formulate the LQR method.

The LQR estimate β is given by

$$\hat{\beta}_{LQR} = \min_{\beta}\left\{\sum_{i=1}^{n}\rho_{\tau}(\mathbf{y}_i - \mathbf{X}_i^T\beta_{\tau}) + k\sum_{j=1}^{p}|\beta_j|\right\},\ k>0 \tag{22}$$

where $i=1,2,\ldots,n;\quad j=1,2,\ldots,p$ and $k>0$ is the regularization parameter controlling the amount of penalty. The second term in Equation (22) is the L_1-penalty, which is required for the Lasso to succeed. As the regularized quantile loss function is convex and piecewise linear, the LQR method can be computed by linear programming.

Two-Stage Regularized and Robust Regression Methods

The robust regression method employed in the study is the QR method. We then combined the two-stage method with regularized and quantile regression methods. The regression methods formulated are Two-stage Ridge Quantile regression and Two-stage Lasso Quantile regression. These regression methods were used to estimate the linear model with autocorrelation and multicollinearity problems.

Two-Stage Ridge Quantile Regression Method

The two-stage process used to alter the data is now used for Ridge Quantile regression to produce the Two-stage Ridge Quantile regression (TRQR) model. We replaced $\mathbf{y}$ and $\mathbf{X}$ in Equation (21) by $\mathbf{y}^*$ and $\mathbf{X}^*$, respectively.

The TRQR estimate β is given by

$$\hat{\beta}_{TRQR} = \min_{\beta}\left\{\sum_{i=1}^{n}\rho_{\tau}(\mathbf{y}_i^* - \mathbf{X}_i^{*T}\beta_{\tau}) + k\sum_{j=1}^{p}(\beta_j)^2\right\},\ k>0 \qquad (23)$$

$i = 1,2,\ldots,n;\quad j = 1,2,\ldots,p$ and $k>0$ is the regularization parameter.

We therefore run the Ridge Quantile regression on $\mathbf{y}^*$ vector of response variable and $\mathbf{X}^*$ matrix of predictors, instead of running it on $\mathbf{y}$ vector of response variable and $\mathbf{X}$ matrix of predictors.

Two-Stage Lasso Quantile Regression Method

The two-stage procedure which was used to arrive at the transformed data is now applied to Lasso quantile regression to produce the Two-stage Lasso Quantile regression (TLQR) method. We now replace $\mathbf{y}$ and $\mathbf{X}$ in Equation (22) by $\mathbf{y}^*$ and $\mathbf{X}^*$, respectively.

The TLQR estimate β is given by

$$\hat{\beta}_{TLQR} = \min_{\beta}\left\{\sum_{i=1}^{n}\rho_{\tau}(\mathbf{y}_i^* - \mathbf{X}_i^{*T}\beta_{\tau}) + k\sum_{j=1}^{p}|\beta_j|\right\},\ k>0 \quad (24)$$

$i = 1,2,\ldots,n;\quad j = 1,2,\ldots,p$ and $k>0$ is the regularization parameter.

We now run the Lasso Quantile regression on $\mathbf{y}^*$ vector of response variable and $\mathbf{X}^*$ matrix of predictors, instead of running the Lasso Quantile regression on $\mathbf{y}$ vector of response variable and $\mathbf{X}$ matrix of predictors.

Performance Criterion

We shall use the Mean Squared Error, MSE, as the main criteria to compare the performances of the regression methods. Also, other performance criteria such the estimating regression coefficients of methods, R-squared, adjusted R-squared, root mean squared error were considered to evaluate the performances of the regression methods. The estimated MSE for each of the regression methods is given by

$$MSE(\hat{\beta}) = \frac{1}{500}\sum_{r=1}^{500}(\hat{\beta}_r - \beta)^T(\hat{\beta}_r - \beta)$$

where $r = 1,2,\ldots,500$, $\hat{\beta}_r$ denote parameter estimated for the r^{th} replication of the experiment and β is the true parameter value. The regression method with the smallest MSE value is considered best.

Data Description

We used both simulated and real datasets. We considered two real datasets in this study: The Portland cement dataset and the Historical dataset. We first checked for the presence of multicollinearity and autocorrelation in the datasets by using the VIF and Durbin-Watson tests. The Portland cement dataset was originally used by Woods, Steinour and Starke (1932). The dataset consists of 13 observations. The response variable is the heat evolved after 180 days of

curing and measured in calories/gram of cement with 40 percent water at 35 degrees Celsius. The four predictor variables considered are the clinker compounds (CALCD) defined as tricalcium aluminate, tricalcium silicate, tetracalcium aluminoferrite and dicalcium silicate.

The Historical dataset was discussed by Bayhan and Bayhan (1998). The dataset consists of 15 observations. The data includes the weekly quantities of shampoos sold as response variable. The two predictor variables are weekly list prices (averages from selected supermarkets) of the firm's shampoos and weekly list prices of a certain brand of soap, substituted from shampoos. Due to the difficulty in obtaining real data with multicollinearity and autocorrelation problems with sample sizes ranging between 25 to 500, we therefore used the two real datasets with sample sizes smaller than 25.

Simulation Design

We evaluated the performance of the regression methods through simulation. Following McDonald and Galarneau (1975) and Kibria (2003), we generated predictor variables as follows

$$x_{ij} = (1-\gamma^2)^{\frac{1}{2}} z_{ij} + \gamma z_{i,p+1} \qquad \text{for } i = 1,2,\ldots,n \quad \text{and} \quad j = 1,2,\ldots,p$$

where z_{ij} is an independent standard normal pseudo random number, and γ is specified so that the theoretical correlation between any two predictor variables is given by γ^2.

The response variable was generated by the equation

$$y_i = \beta_0 + \beta_1 x_{i1} + \beta_2 x_{i2} + \ldots + \beta_p x_{ip} + \mu_i .$$

The model parameters are assumed to be unity and β_0 is taken to be zero. The μ_i are generated from AR (1) process as

$$\mu_i = \rho\mu_{i-1} + e_i, \quad i = 1, 2, \ldots, n$$

where e_i are independent normal pseudo random numbers and ρ is autoregressive coefficient such that $|\rho| < 1$. The error terms were generated by assuming $e_i \sim N(0,1)$ and using the distributional property of the autocorrelated error terms $\mu_i \sim N\left(0, \frac{\sigma_e^2}{1-\rho^2}\right)$.

The design was performed by varying multicollinearity levels, the number of predictor variables, sample sizes and degrees of autocorrelation as shown:

1) Multicollinearity levels (0.7, 0.9 and 0.99)
2) Number of predictor variables (2, 4 and 8)
3) Sample size (25, 50, 200 and 500)
4) Degrees of autocorrelation (0.1 and 0.9)

We want to see the effect of the sample sizes, number of predictor variables, multicollinearity levels and degrees of autocorrelation on the performance of the regression methods discussed in this study. The simulation was replicated 500 times in order to obtain the approximate distribution.

Chapter Summary

Various regression methods that would be used in the study have been reviewed. These include OLS, RR, Lasso, TR, TLasso, QR, RQR, LQR, TRQR and TLQR. The concept of regularization of linear models has also been explained. In line with this, techniques of regularization processes have also

been reviewed. These are the L_1 and L_2 penalties of regularization. A discussion of Quantile regression as a robust regression method was done. The study employed three quantile levels (0.25, 0.5 and 0.75). Quantile regression with Ridge and Lasso regularization to develop quantile regression models were formulated. It is anticipated that quantile regression with regularization could improve models.

Two-stage procedure was introduced and $\mathbf{P}$ transformation matrix was adopted to be used to transform the datasets to correct for autocorrelation. To deal with multicollinearity and autocorrelation simultaneously, the chapter presents the combination of two-stage method with regularized and quantile regression methods. The data employed in the study consists of simulated and two real datasets. The simulation design was presented. Various performance criteria have been stated, which would be needed to determine the method that best addresses the problems of multicollinearity and autocorrelation simultaneously. These are MSE, root mean squared error, adjusted R-squared and R-squared. The MSE happened to be the main performance criteria for comparing the performances of the regression methods.

CHAPTER FOUR

RESULTS AND DISCUSSION

Introduction

This chapter analyses and discusses the results from our simulated and real application datasets. The study examines different regularized and robust regression methods for handling multicollinearity and autocorrelation problems. It presents results of performances of different regression methods, namely, Ordinary Least Squares Regression (OLS), Ridge Regression (RR), Lasso Regression, Two-Stage Ridge Regression (TR), Two-Stage Lasso Regression (TLasso), Quantile Regression (QR), Ridge Quantile Regression (RQR), Lasso Quantile Regression (LQR), Two-Stage Ridge Quantile Regression (TRQR), and Two-Stage Lasso Quantile Regression (TLQR). The analyses were done in two parts. Firstly, appropriate data was simulated and then the regression models were fitted using different regression methods. The MSEs of the different regression methods were computed and compared to know the best regression method for the simulated dataset. Secondly, the regression models were fitted to the real datasets described earlier. The MSEs of the different regression methods as well as other statistical values (such as regression coefficients, R-squared, adjusted R-squared, RMSE) were computed and compared to know the best regression method by applying real dataset.

Statistical Packages

The R software program was used for the analysis of the data at various stages of the study. Algorithms for data simulations were written in R language. The R software program was used to simulate data, and for analysing the simulated and real datasets. R is a software environment and programming

language for statistical computing. R has been widely used in research data analysis. The data analysis in R is done by writing scripts and functions. The following packages (or libraries) in R were employed in the analysis of the simulated dataset and the real dataset; MASS, lmridge, islasso, quantreg, hqreg, glmnet, lrmest, and the lmtest package.

The ordinary least squares regression was performed by the 'MASS' R package. For ridge regression (and two-stage ridge regression) we employed the R package 'lmridge', for Lasso regression (and two-stage Lasso regression) we employed the R package 'islasso', for quantile regression we employed the R package 'quantreg', for ridge quantile regression (and two-stage ridge quantile regression) and Lasso quantile regression (and two-stage Lasso quantile regression) we employed the R package 'hqreg'. The 'lrmest' R package was used to check the multicollinearity degree present in the dataset and the 'lmtest' R package was used to perform the Durbin-Watson test for autocorrelation of errors.

Simulation Study

Autocorrelation and multicollinearity are two of the most common regression analysis problems. We usually think of these two problems separately; however, they can occur concurrently in applied situations. A Monte Carlo simulation was designed to assess the regularized and robust regression methods performances. We designed dataset with 0.7, 0.9 and 0.99 multicollinearity levels with 0.1 degree of autocorrelation and another dataset with 0.7, 0.9 and 0.99 multicollinearity levels with 0.9 degree of autocorrelation. For both settings we use two, four and eight predictor variables with different

sample sizes; n = 25, 50, 200 and 500. The number of replications used for the simulation is 500 Monte Carlo simulations.

Autocorrelation degrees of 0.1 and 0.9 were utilized, resulting in autocorrelation for some models and no autocorrelation for others. The sensitivity of the methods was assessed by varying the multicollinearity degrees from 0.7 to 0.9 and 0.99. Sample sizes of 25, 50, 200, and 500 were utilized to ensure that the sample size ranged from small to moderate to large. The simulation runs of 500 does not take too much time to run and it is considered sufficient to produce stable estimates of the results. The same setting is used for all the methods and their mean square error (MSE) computed. All methods may thus be compared on the same level, and their MSEs can be directly compared.

Simulation Results for Two Predictor Variables

The MSE values as well as the regression coefficients of the regression methods are computed. Due to the voluminous nature of the regression coefficients generated for all the methods, only few are presented in the work and the rest in Appendix B. The Table 1 to Table 4 are some of the simulation results of regression coefficients for two predictor variables.

Based on 500 Monte Carlo Simulations

Table 5 shows the simulation results of the estimated MSEs for two predictor variables when ρ = 0.1. Based on the MSE of each regression method, the TR has the least MSE as compared to the other methods for all categories. Consequently, RR and TR methods are better than OLS when the multicollinearity problem exists in a data with TR being the best in this case for the two predictor variables. It clearly indicates that the estimated mean squared errors for TR is always less than that of RR method. The simulation results show that the TR method performs better than OLS, RR, Lasso and TLasso for all samples sizes (*n* = 25, 50, 200 and 500) and across the different levels of

multicollinearity (0.7, 0.9 and 0.99). In addition, we observe that the performance of Lasso and TLasso methods to the OLS method is not satisfactory with large sample size. The results show that the estimated MSE for the OLS method competes with Lasso and TLasso methods with large sample sizes ($200 \leq n \leq 500$) for two predictor variables. The findings from comparisons of the OLS, RR, Lasso, TR and TLasso methods show that the TR method is better than other methods (OLS, RR, Lasso and TLasso), and much better than OLS method.

Table 6: **Estimated MSE for Two Predictor Variables when ρ = 0.9**

γ^2	n	OLS	RR	Lasso	TR	TLasso
0.7	25	3.09038	2.94315	3.11001	**2.92748**	3.09169

	500	4.99047	4.97904	4.98852	**4.97896**	4.98839

Based on 500 Monte Carlo Simulations

Table 6 presents the simulation results of the estimated MSEs for two predictor variables when ρ = 0.9. Based on the MSE of each regression method, the TR has the least MSE among the other regression methods for all sample sizes (n = 25, 50, 200 and 500) and across the different levels of multicollinearity (0.7, 0.9 and 0.99). Consequently, RR and TR methods are better than OLS, Lasso and TLasso, with TR being the best in this case for the two predictor variables. It clearly indicates that the estimated mean squared errors for TR is always less than that of RR when the multicollinearity and autocorrelation problems exist in a dataset. We observe that the performance of Lasso and TLasso as compared to the OLS is not satisfactory for large sample size (n = 500). The results show that the MSE for OLS method is relatively smaller than the Lasso and TLasso methods with large sample size. The estimated MSEs of Lasso and TLasso decreases as the multicollinearity level increases for a decreased sample size. The results of comparison indicated that, the TLasso method outperforms the OLS for combinations of multicollinearity and autocorrelation problems when the degree of multicollinearity is high with small sample sizes. The estimated MSEs of TLasso method gets closer to the estimated MSEs of TR method for increased sample size. However, the TR method seems to be an appropriate alternative to other methods in handling autocorrelation and multicollinearity problems.

Based on 500 Monte Carlo Simulations

In Table 7, we provide the results of estimated MSEs of the methods for two predictor variables when τ = 0.25. When ρ = 0.1, RQR, TRQR and TLQR methods outperforms the other methods. Comparing TRQR and TLQR methods, TRQR performs better than TLQR with large sample sizes (*n* = 500).

Whiles, TLQR produce better results than TRQR with small sample sizes (n = 25). When ρ = 0.9, TRQR and TLQR methods outperforms the other methods except on two cases where RQR and LQR methods produced better MSE results.

Table 8: **Estimated MSE for Two Predictor Variables when τ = 0.5**

Based on 500 Monte Carlo Simulations

Table 8 is the estimated MSEs of the methods for two predictor variables when $\tau = 0.5$. The two scenarios considered in the simulation studies are when $\rho = 0.1$ and $\rho = 0.9$. Based on the mean square errors for each model, we noted that all regression methods with $\tau = 0.5$ are better than regression methods when $\tau = 0.25$ and $\tau = 0.75$ (comparing Table 7, Table 8 and Table 9) for $\rho = 0.1$ and $\rho = 0.9$.

The simulation results from the first scenario when $\rho = 0.1$ indicated that, the MSE values of TLQR methods at $\tau = 0.5$ are relatively smaller than that of the TRQR methods at $\tau = 0.5$ in all the cases, except two cases where the MSE values of TRQR methods at $\tau = 0.5$ are relatively smaller than TLQR methods at $\tau = 0.5$. Also, RQR produce better results than LQR with less predictor variables and small sample size.

The simulation results from the second scenario when $\rho = 0.9$ indicated that, TRQR and TLQR methods at $\tau = 0.5$ outperforms the other methods in all the cases. Comparing TRQR and TLQR methods at $\tau = 0.5$, the TRQR produce better results than TLQR with less predictor variables and small sample sizes whiles TLQR performs better with larger sample size.

Based on 500 Monte Carlo Simulations

The comparison of the performances of the methods in term of their MSE values over two predictor variables at various levels of multicollinearity and sample size is given for both ρ = 0.1 and ρ = 0.9 in Table 10. The simulation findings when ρ = 0.1 revealed that, TR method outperforms the other methods

in many of the cases, especially with severe multicollinearity. Increasing multicollinearity provides an overall improvement in TR over the other regression methods for two predictor variables. Moreover, the LQR and TLQR methods at quantile level 0.5 often competes favourably with the TR method.

The simulation results when $\rho = 0.9$ revealed that, the TR method has the smallest MSE values and therefore outperforms the other methods with high autocorrelation and across the different degrees of multicollinearity, except three of the cases where TLQR method at quantile level 0.5 performs best. For $25 \leq n \leq 200$, TR is best when multicollinearity is high with high autocorrelation for two predictor variables. Moreover, with large sample size (n = 500), the TLQR method at quantile level 0.5 is best. Overall, the use of the TR method for two predictor variables in a model is generally effective in handling multicollinearity and autocorrelation problems.

Simulation Results for Four Predictor Variables

The MSE values together with the regression coefficients are computed for all the regression methods. However, few of the regression coefficients of the methods are presented due to its voluminous nature and the rest in Appendix B. The Table 11 to Table 13 are some of the simulation results of regression coefficients for four predictor variables.

Table 11: **Coefficients for Four Predictors when $\gamma^2 = 0.90$, $\rho = 0.9$ and $n = 500$**

Based on 500 Monte Carlo Simulations

Table 14 presents the simulation results of estimated MSEs for four predictor variables when ρ = 0.1. The results clearly indicate that the estimated mean squared errors for TR is always less than that of RR method. The simulation results therefore showed that the TR method outperforms OLS, RR, Lasso and TLasso methods for all the different samples sizes (*n* = 25, 50, 200 and 500) and across the different degrees of multicollinearity (0.7, 0.9 and 0.99). Again, we can see that the performance of Lasso and TLasso methods to the OLS method is not satisfactory for large sample size. The results show that the MSE for the OLS method competes with Lasso and TLasso methods with large

sample sizes ($200 \leq n \leq 500$) for four predictor variables. However, the Lasso and TLasso methods perform better than the OLS method for a very high multicollinearity ($\gamma^2 = 0.99$) across all samples size (n = 25, 50, 200 and 500). The findings from comparisons of the OLS, RR, Lasso, TR and TLasso methods show that, the TR method outperforms the other methods (OLS, RR, Lasso and TLasso), and much better than OLS method.

Table 15: **Estimated MSE for Four Predictor Variables when ρ = 0.9**

γ^2	n	OLS	RR	Lasso	TR	TLasso
0.7	25	2.68242	2.51313	2.66882	**2.49036**	2.63958

	500	5.92468	5.90764	5.91089	**5.90748**	5.91082

Based on 500 Monte Carlo Simulations

Table 15 presents the simulation results of the estimated MSEs for four predictor variables when ρ = 0.9. According to the MSE criterion of each regression method, the TR method has the least MSE among the other

regression methods (OLS, RR, Lasso and TLasso) for all sample sizes (n = 25, 50, 200 and 500) and across the levels of multicollinearity (0.7, 0.9 and 0.99). Moreover, the RR method on the other hand outperforms OLS, Lasso and TLasso methods in the above-mentioned categories. However, the estimated mean squared errors for TR method are always less than that of RR when the multicollinearity and autocorrelation problems exist in a dataset. The estimated MSEs of Lasso and TLasso methods decreases as the multicollinearity level increases for a decreased sample size.

The results of comparison indicated that, the Lasso and TLasso methods are better than the OLS method in existence of autocorrelation and multicollinearity problems. But with a very large sample size, OLS method is a close competitor to the Lasso and TLasso methods with respect to their MSEs. The superiority of the Lasso and TLasso methods over OLS is primarily determined by the degree of autocorrelation and the number of predictors in the data. The estimated MSEs of TLasso method gets closer to the estimated MSEs of TR method for large sample size. Therefore, the TR method seems to be an appropriate alternative to other methods in existence of autocorrelation and multicollinearity issues.

Based on 500 Monte Carlo Simulations

In Table 16, we provide the results of estimated MSEs of the methods for four predictor variables when τ = 0.25. When ρ = 0.1, QR, RQR, TRQR and TLQR methods performed in various cases except LQR method which did not perform in any case. The QR method improved in performance with large

sample sizes. When ρ = 0.9, TRQR method performs better than the other methods except on three cases where RQR and TLQR methods produced better MSE results.

Based on 500 Monte Carlo Simulations

Table 17 provides the simulation results of estimated MSEs of the methods for four predictor variables when $\tau = 0.5$. The two scenarios considered in the simulation studies are the cases when the degrees of the autocorrelation are at 0.1 and 0.9. Based on the MSE criterion for each regression method, we noted that all regression methods with $\tau = 0.5$ outperforms regression methods with $\tau = 0.25$ and $\tau = 0.75$ (see Table 16, Table 17 and Table 18).

The simulation results for the first scenario when $\rho = 0.1$, show that the MSEs of the TLQR methods at $\tau = 0.5$ are relatively smaller than the TRQR methods at $\tau = 0.5$, except two cases where MSE values of TRQR methods at $\tau = 0.5$ are relatively smaller than TLQR methods at $\tau = 0.5$. In fact, RQR is a close competitor with LQR in a model with less predictor variables. But the results from comparisons of the methods show that, TLQR methods at $\tau = 0.5$ are most preferred methods with very high multicollinearity level $(\gamma^2 = 0.99)$ at the different samples size (n = 25, 50, 200 and 500).

The simulation findings for the second scenario when $\rho = 0.9$ revealed that, the TRQR and TLQR methods at $\tau = 0.5$ outperforms the other methods in all the cases. It can be noticed that in all the considered situations for $\rho = 0.9$, TLQR at $\tau = 0.5$ has the least MSE and outperforms RQR, LQR and TRQR at all quantile levels. There is only one case, where TRQR at $\tau = 0.5$ outperforms TLQR, however, the difference in MSE values between the two methods appears to be small. Therefore, the TLQR method is better than the other methods (QR, RQR, LQR and TRQR) in handling multicollinearity and autocorrelation problems in a dataset for four predictor variables.

Based on 500 Monte Carlo Simulations

Table 18 provides the simulation results of estimated MSEs of the methods for four predictor variables when τ = 0.75. When ρ = 0.1, RQR and TRQR are the best performing methods as well as QR method competing at large sample sizes (*n* = 500). When ρ = 0.9, RQR method performs better than the other

methods except on three cases where LQR, TRQR and TLQR methods produced better MSE results.

Based on 500 Monte Carlo Simulations

The summary of the performances of the methods in term of their MSE values over four predictor variables at various levels of multicollinearity and

sample size is given for both ρ = 0.1 and ρ = 0.9 in Table 19. When ρ = 0.1, RQR, LQR and TLQR methods at quantile level 0.5 outperforms the other methods except on one case where TR method is best when *n* = 25 at 0.9 multicollinearity level. The TLQR method produce better results than the other methods with severe multicollinearity $(\gamma^2 = 0.99)$ for the different samples size. When $\gamma^2 = 0.7$, the pattern of the findings is similar to when $\gamma^2 = 0.9$ and 0.99 for high autocorrelation $(\rho = 0.9)$. When $n = 25$ and $n = 500$, the TR method is best except when $50 \le n \le 200$. Moreover, when $50 \le n \le 200$, the TLQR method at quantile level 0.5 is generally best. Therefore, both TR method and TLQR method at quantile level 0.5 are the best methods in handling multicollinearity and autocorrelation problems in a dataset with four predictors.

Simulation Results for Eight Predictor Variables

The MSE values and regression coefficients were computed for all the regression methods. All estimated MSE values for all the regression methods are presented. The coefficients of the methods are in Appendix B. However, few of the simulation results of regression coefficients of the regression methods for eight predictor variables are presented as in Table 20 and Table 21.

Based on 500 Monte Carlo Simulations

Table 22 presents the simulation results of estimated MSEs for eight predictor variables when ρ = 0.1. The results indicate that the OLS is the least effective method among the others. According to the results, we observed that, increasing the degree of multicollinearity between the predictor variables has an adverse effect on the OLS method's MSE values. In all the considered cases, the TR method is superior to the other methods. Except in two cases where TLasso excels and TR is a close competitor. We observed that with large number of predictors, TLasso has a significantly lower MSE value, corresponding to a smaller sample size.

Again, we observed that the performance of OLS method performs better than Lasso and TLasso methods as the sample size increases with multicollinearity level not being too high. The results show that the estimated MSE for the OLS method competes with Lasso and TLasso methods with large samples sizes ($200 \leq n \leq 500$) for eight predictor variables. However, Lasso and TLasso methods perform better than the OLS method for a very high multicollinearity ($\gamma^2 = 0.99$) across all sample size (n = 25, 50, 200 and 500). It can be seen that Lasso and TLasso methods performs better with increase predictor variables. The findings from comparisons of the OLS, RR, Lasso, TR and TLasso methods reveals that the TR method is superior to the other methods, and much better than OLS method.

Based on 500 Monte Carlo Simulations

Table 23 presents the simulation results of the estimated MSEs for eight predictor variables when ρ = 0.9. The results reveal how the TR method is superior to the other regression methods, except in two cases, where TR is a close contender to TLasso in terms of performance. It is clear from the results that with large number of predictors, TLasso has a significantly lower MSE value. We observed from the results that, OLS is the worst performing method as compared to the regularized and robust methods. Moreover, the RR method on the other hand outperforms OLS, Lasso and TLasso methods in the above-mentioned categories, except in two cases where TLasso is superior. Also, the

estimated MSEs for TR method is always less than that of RR method when the multicollinearity and autocorrelation problems exist in a dataset.

The results of comparison indicated that, Lasso and TLasso methods outperforms the OLS method. However, with a very large sample size and high multicollinearity level $(\gamma^2 = 0.7)$, OLS method turns to compete with the Lasso and TLasso methods. The better performance of the Lasso and TLasso methods over OLS largely depends on the number of predictors, autocorrelation degree and multicollinearity level in the data. The MSEs of TLasso method is relatively smaller than the estimated MSEs of TR method for large sample sizes ($200 \leq n \leq 500$) with very high multicollinearity level $(\gamma^2 = 0.99)$. Therefore, the TR method seems to be an appropriate alternative to other methods in handling multicollinearity and autocorrelation issues in a dataset.

Based on 500 Monte Carlo Simulations

Table 24 is the results of estimated MSEs of the methods for eight predictor variables when τ = 0.25. When ρ = 0.1, RQR and TRQR methods outperforms the other methods except on two cases where LQR and TLQR methods showed relatively smaller MSEs. When ρ = 0.9, RQR, LQR, TRQR and TLQR methods

performed in various cases except QR method which did not perform in any case.

Based on 500 Monte Carlo Simulations

Table 25 shows the simulation results of estimated MSEs of the methods for eight predictor variables. The two scenarios considered in the simulation studies are when $\rho = 0.1$ and $\rho = 0.9$. Based on the MSE criterion for each regression method, it can be seen that all regression methods with $\tau = 0.5$ outperforms regression methods with $\tau = 0.25$ and $\tau = 0.75$ (Comparing Table 24, Table 25 and Table 26). The simulation results when $\rho = 0.1$ in Table 20 show that, the TLQR method at quantile level 0.5 has the least MSE values and therefore outperforms the other regression methods with small sample sizes ($25 \leq n \leq 50$). However, LQR method at quantile level 0.5 performs better than the other regression methods with large samples size ($200 \leq n \leq 500$) for eight predictor variables.

The simulation results when $\rho = 0.9$ is also presented in Table 25. According to the MSE criterion of each regression method, the TLQR method at quantile level 0.5 has the least MSE values in comparison to the other regression methods (QR, RQR, LQR and TRQR) for all sample size (n = 25, 50, 200 and 500) and across the various degrees of multicollinearity (0.7, 0.9 and 0.99). Therefore, the TLQR method appears to be an appropriate alternative to other regression methods in handling multicollinearity and autocorrelation problems in a dataset.

Table 26: **Estimated MSE for Eight Predictor Variables when τ = 0.75**

Based on 500 Monte Carlo Simulations

The comparison of the performances of the methods in term of their MSE values over eight predictor variables at various levels of multicollinearity and

sample sizes is given for both ρ = 0.1 and ρ = 0.9 in Table 27. The simulation findings when ρ = 0.1 indicated that, LQR and TLQR methods at quantile level 0.5 outperforms the other methods in all the cases, except one case where TR method is the best when $n = 25$ at 0.7 degree of multicollinearity. Comparing LQR and TLQR methods at quantile level 0.5, LQR performs better than TLQR with large sample sizes ($200 \leq n \leq 500$). Whiles, TLQR produce better results than LQR with small sample sizes ($25 \leq n \leq 50$).

The simulation results when ρ = 0.9 indicated that, TLQR method at quantile level 0.5 outperforms the other methods when the autocorrelation is high and across the different degrees of multicollinearity, except in two cases where TR is superior. However, for $25 \leq n \leq 50$ with high autocorrelation and severe multicollinearity, TR is best. With large sample sizes, the TLQR at quantile level 0.5 is best. The study showed that the use of the TLQR method in the cases when the predictor variables are affected by multicollinearity and autocorrelation is one of the successful ways to solve this issue.

Real Data Application

We investigate the performances of the regression methods on two real applications: The Portland cement dataset and the Historical dataset.

Analysis of Portland Cement Data

This dataset was originally used by Woods, Steinour and Starke (1932). The data includes the heat evolved in calories per gram of cement (y) as dependent variable and four ingredients as predictor variables: tricalcium aluminate (X_1), tricalcium silicate (X_2), tetracalcium aluminoferrite (X_3) and dicalcium silicate (X_4).

Table 28: **Descriptive Statistics of Variables**

Variable	N	Min	Max	Mean	Std. Deviation	Skewness	Kurtosis
y	13	72.50	115.90	95.42	15.044	-0.195	1.658
X_1	13	1.00	21.00	7.46	5.882	0.688	3.075
X_2	13	26.00	71.00	48.15	15.561	-0.047	1.677
X_3	13	4.00	23.00	11.77	6.405	0.611	1.921
X_4	13	6.00	60.00	30.00	16.738	0.330	1.986

Source: Researcher's Computation (2022)

Table 28 presents the descriptive statistics for the Portland cement data. For y and X_1, the highest and lowest means are recorded respectively. The standard deviations for each variable indicate that the deviations are bigger. We observed that the predictors appear to be right-skewed, except X_2 variable which appears to be left-skewed. The coefficient of skewness is low, this show that the data are fairly symmetrical. The variables exhibit low kurtosis and tend to have light tails. This means that there are less values in the tails compared to a normal distribution, which further signified lack of outliers. Generally, the low values of kurtosis and skewness suggest that the variables' distribution are quite close to normality.

Table 29: **Correlation Matrix of Predictor Variables of the Original Data**

Variables	X_1	X_2	X_3	X_4
X_1	1.000			
X_2	0.229	1.000		
X_3	-0.824	-0.139	1.000	
X_4	-0.245	-0.973	0.030	1.000

Source: Researcher's Computation (2022)

Table 29 is the correlation matrix which presents the correlation among the variables in the data. The smallest correlation of 0.030 was obtained between X_3 and X_4, suggesting that there may be no statistically significant association between the two variables. The strongest correlation, -0.973, was found between X_2 and X_4, suggesting that the two variables can be considered very highly correlated and have much in common. The correlation coefficient of -0.824 shows fairly strong negative relationship between X_1 and X_3, and that the two variables can be considered highly correlated. The high correlation between the variables may suggest a possible presence of multicollinearity in the data.

Table 30: **VIF and Durbin-Watson Test of the Original Data**

VIF_1	VIF_2	VIF_3	VIF_4	dl	du	DW	p-value	α	ρ
38.50	254.42	46.87	282.51	0.574	2.094	2.053	0.421	0.05	-0.09

Source: Researcher's Computation (2022)

Table 30 presents the VIF and Durbin-Watson test of the original data. The DW statistic and the p-value are 2.053 and 0.421, respectively. The results show that $dl < DW < du$, this means, the test is inconclusive. However, the p-value (p = 0.421 > 0.05) from the Durbin-Watson test concludes that there is no autocorrelation in the error term at the 5% significance level with dl = 0.574 and du = 2.094. Moreover, all the variance inflation factors exceed 10. It is evident from the VIFs that the data suffers from the problem of multicollinearity. Therefore, we obtained an estimate of rho (ρ) and use the estimate of rho (ρ = -0.09) to transform the original data.

Table 31: **Correlation Matrix of Predictor Variables of the Transformed Data**

Variables	X_{1T}	X_{2T}	X_{3T}	X_{4T}
X_{1T}	1.000			
X_{2T}	0.246	1.000		
X_{3T}	-0.786	-0.066	1.000	
X_{4T}	-0.270	-0.980	-0.015	1.000

Source: Researcher's Computation (2022)

Table 31 presents the correlation matrix of the transformed variables. It was observed that the transformed variables X_1T and X_3T are highly negatively correlated with each other with correlation coefficient of -0.786, and therefore suggests that a linear relationship exists among them. The highest correlation of -0.980 was obtained between X_2T and X_4T, suggesting that the two variables are very highly correlated. Therefore, the high correlation between the transformed variables suggests a possible existence of multicollinearity in the data.

Table 32: **VIF and Durbin-Watson Test of the Transformed Data**

VIF_1	VIF_2	VIF_3	VIF_4	dl	du	DW	p-value	α
10.06	91.18	11.05	103.30	0.574	2.094	2.218	0.619	0.05

Source: Researcher's Computation (2022)

Table 32 presents the VIF and Durbin-Watson tests of the transformed data. The transformed data was diagnosed using the VIF and the Durbin-Watson (DW) tests. The DW statistic and the p-value are 2.218 and 0.619, respectively. The results show that $DW > du$, therefore the data does not suffer from first

order autoregressive scheme. However, since the values for *VIF* of all the predictor variables are greater than 10 ($VIFs > 10$), the model still suffer from multicollinearity.

Table 33: **Regression Analysis Results for Ordinary Least Square (OLS)**

Variable	Estimate	Std. Error	*t* value	*p*-value
Intercept	62.4054	70.0710	0.891	0.3991
X_1	1.5511	0.7448	2.083	0.0708
X_2	0.5102	0.7238	0.705	0.5009
X_3	0.1019	0.7547	0.135	0.8959

R-squared	0.9824			
Adj. R-squared	0.9736			
MSE	5.9830			
RMSE	2.4460			
F-statistic: *F* (4, 8)	111.5		*p*-value	0.0000

Source: Researcher's Computation (2022)

Table 33 presents the estimated MSE, R-squared value and regression coefficients of OLS method. According to regression analysis results conducted by using OLS method, regression coefficients of all the predictors were found to be statistically insignificant at 5% significance level. However, the *F*-statistic for the overall model is significant [*F* (4, 8) = 111.5, *p*-value = 0.0000]. The OLS regression coefficients appears to have high standard errors. This may be as a result of the presence of multicollinearity which has excessively inflates the standard error, and has cause the regression coefficients to appear insignificant. The R-squared value of 0.9824 means the predictor variables can explain 98.24% of the variation in the response variable. The MSE of the OLS method is obtained as 5.9830.

Table 34: **Regression Analysis Results for Ridge Regression (RR)**

Variable	Estimate	Std. Error	*z* value	*p*-value
Intercept	74.8025	51.5924	1.450	0.1471

RMSE	2.4117			
K	0.97701			

Source: Researcher's Computation (2022)

Table 34 presents the estimated MSE, R-squared value and regression coefficients of RR method. According to regression analysis results conducted by using RR method, the variable X_1 has a significant effect on the dependent variable according to *p*-value (0.0104) at 5% significance level. The results of the analysis show a decrease in the standard error of the RR method in comparison to the OLS method. The R-square (0.9823) reveals that the predictors explain 98.23% of the variation in the response variable. The MSE and RMSE values are 5.8161 and 2.4117 respectively, when the value of K = 0.97701.

Table 35: **Regression Analysis Results for Lasso Regression**

Variable	Estimate	Std. Error	*z* value	*p*-value
Intercept	65.3456	69.4081	0.941	0.3465
X_1	1.5192	0.7381	2.058	0.0396

Table 35 presents the estimated MSE, R-squared value and regression coefficients of Lasso method. The regression analysis results conducted by using Lasso method revealed that the variable X_1 has a significant effect on the response variable according to *p*-value (0.0396) at 5% level of significance. The standard errors of the Lasso method show relatively small decrease to that of the OLS method. The R-square (0.9824) shows that 98.24% variation in the response variable can be explained by the predictors. The MSE and RMSE values obtained by the Lasso method are 5.9775 and 2.4449 respectively, when the value K is 0.18307.

Table 36: **Regression Analysis Results for Two-Stage Ridge Regression (TR)**

Variable	Estimate	Std. Error	*z* value	*p*-value
Intercept	30.2745	37.5707	0.806	0.4204
X_1T	1.8909	0.4281	4.417	0.0000
X_2T	0.8406	0.3899	2.156	0.0311
X_3T	0.4363	0.4224	1.033	0.3017

Table 36 presents the regression analysis results for TR method. According to regression analysis results conducted by using TR method, regression coefficients of the X_1T and X_2T variables were found to be statistically significant at 5% level of significance. The TR standard errors are decreased compared to OLS. The smaller the TR method standard error, the better the regression models fit to the data. The R-square (0.9843) shows that 98.43% variation in the response variable can be explained by the predictors. The MSE and RMSE values computed are 5.7399 and 2.3958 respectively, when the value of K = 0.001.

Table 37: **Regression Analysis Results for TLasso Regression**

Variable	Estimate	Std. Error	*z* value	*p*-value
Intercept	53.1040	67.8494	0.783	0.4338
X_1T	1.6562	0.7226	2.292	0.0219
X_2T	0.6055	0.7006	0.864	0.3875

K	0.001			

Source: Researcher's Computation (2022)

Table 37 presents the regression analysis results for TLasso method. The regression analysis results conducted by using TLasso method revealed that the variable X_1T has a significant effect on the response variable according to *p*-value (0.0219) at 5% significance level. The TLasso method standard errors are relatively smaller in comparison to OLS method. The R-square (0.9845) shows that the predictor variables can explain 98.45% of the variation in the response variable. The MSE and RMSE values obtained by the TLasso method are 5.9630 and 2.4419 respectively, when the value K is 0.001.

Table 38: **Comparison of Regression Coefficients and MSEs of the Methods**

Coefficient	OLS	RR	Lasso	TR	TLasso
β_0	62.4054	74.8025	65.3456	30.2745	53.1040
β_1	1.5511	1.4159	1.5192	1.8909	1.6562
β_2	0.5102	0.3841	0.4803	0.8406	0.6055
β_3	0.1019	-0.0335	0.0696	0.4363	0.1972
β_4	-0.1441	-0.2682	-0.1735	0.1814	-0.0500
R-squared	0.9824	0.9823	0.9824	0.9843	0.9845
Adj. R-squared	0.9736	0.9735	0.9736	0.9765	0.9768
MSE	5.9830	5.8161	5.9775	5.7399	5.9630
RMSE	2.4460	2.4117	2.4449	2.3958	2.4419

Source: Researcher's Computation (2022)

Table 38 presents the regression coefficients and MSEs of the methods. According to the regression coefficients, the regression methods results are similar to each other. The findings reveal that the TR method has the lowest MSE value (5.7399) than the other methods, however, the TLasso method has the highest R-squared value (0.9845). The TR method has the least MSE and RMSE, and is considered best. Because of the existence of multicollinearity, the OLS method produces the worst results. Therefore, the TR method is most preferred method in fitting a linear model when the multicollinearity assumption is violated.

Table 39: **Comparison of QR Methods for τ = 0.25, 0.5 and 0.75**

Coefficient	QR		
	τ = 0.25	τ = 0.5	τ = 0.75
β_0	48.0545	-13.3367	47.6909
β_1	1.4976	2.3544	1.7084
β_2	0.7000	1.2798	0.6623
β_3	-0.0025	1.0074	0.3564
β_4	0.0296	0.6006	-0.0085
R-squared	0.9647	0.9775	0.9770
Adj. R-squared	0.9471	0.9663	0.9655
MSE	11.9769	7.6260	7.8119
RMSE	3.4608	2.7615	2.7950

Source: Researcher's Computation (2022)

Table 39 presents the regression coefficient estimation and the MSE at the 0.25, 0.5 and 0.75 quantile levels for QR. The intercept term at quantile level 0.25 and 0.75 has a positive sign while that of the quantile level at 0.5 has a negative sign. This might be due to the multicollinearity effect in the data. QR method at quantile level 0.5 has the lowest MSE and the highest R-squared value. The method is considered the best in this class of methods. However, the coefficients may not be estimated with great precision due to the existence of the multicollinearity in the data.

Table 40: **Coefficients and MSEs of RQR and LQR Methods**

Coefficient	RQR			LQR		
	$\tau = 0.25$	$\tau = 0.5$	$\tau = 0.75$	$\tau = 0.25$	$\tau = 0.5$	$\tau = 0.75$

Source: Researcher's Computation (2022)

The results presented in Table 40 shows the regression coefficient estimation and the MSE at the 0.25, 0.5 and 0.75 quantile levels for RQR and LQR. These methods allow the estimation of the quantile regression models using the L_1 and L_2-norms. We compare the performance of the quantile levels in RQR and LQR. The results through comparisons, we found that the RQR at quantile level 0.75 is the best as it has a high R-squared value (0.9742) and the least MSE value (5.3820) according to the interpretation of the data regarding the issues under study.

Table 41: **Coefficients and MSEs of TRQR and TLQR Methods**

Coefficient	TRQR			TLQR		
	$\tau = 0.25$	$\tau = 0.5$	$\tau = 0.75$	$\tau = 0.25$	$\tau = 0.5$	$\tau = 0.75$

RMSE	3.8501	2.1798	2.8624	3.4587	2.0018	2.5012

Source: Researcher's Computation (2022)

Table 41 presents the regression coefficient estimation and the MSE at the 0.25, 0.5 and 0.75 quantile levels for TRQR and TLQR. We therefore compared the performances of the quantile levels in TRQR methods and TLQR methods. We found that the TLQR at quantile level 0.5 is the best as it has a high R-squared value (0.9831) and the smallest MSE value (4.0073). The results show that the TLQR at quantile level 0.5 produced the most efficient estimates in terms of high R-square, lower RMSE and smallest MSE.

Table 42: **Comparison of TR, TLasso, TRQR and TLQR Methods**

Coefficient	TR	TLasso	TRQR	TLQR
			$\tau = 0.5$	$\tau = 0.5$
β_0	30.2745	53.1040	57.4066	15.9491
β_1	1.8909	1.6562	1.7234	2.0725
β_2	0.8406	0.6055	0.5969	0.9978
β_3	0.4363	0.1972	0.3035	0.6296
β_4	0.1814	-0.0500	-0.0903	0.3267
R-squared	0.9843	0.9845	0.9800	0.9831
Adj. R-squared	0.9765	0.9768	0.9700	0.9747
MSE	5.7399	5.9630	4.7516	4.0073
RMSE	2.3958	2.4419	2.1798	2.0018

Source: Researcher's Computation (2022)

Table 42 presents the overall comparison of the performances of TR, TLasso, TRQR and TLQR methods. Based on the R-squared values of the methods, TLasso appears best with respect to variation the predictor variables can explain in the response variable. According to the MSE criterion of each regression method, the TLQR method at quantile level 0.5 has the least MSE in comparison to the other methods. The results from comparisons of the TR, TLasso, TRQR at quantile level 0.5 and TLQR at quantile level 0.5 methods show that the TLQR method at quantile level 0.5 is superior to the other methods. Therefore, the TLQR method in the cases when the predictor variables are affected by multicollinearity is one of the successful ways to solve this issue.

Analysis of Historical Data

This dataset was discussed by Bayhan and Bayhan (1998). The data includes the weekly quantities of shampoos sold (y) as dependent variable and two predictor variables: weekly list prices (averages from selected supermarkets) of the firm's shampoos (X_1) and weekly list prices of a certain brand of soap, substituted from shampoos (X_2).

Table 43: **Summary Statistics of Variables**

Variable	N	Min	Max	Mean	Std. Deviation	Skewness	Kurtosis
y	15	34.16	35.17	34.59	0.320	0.427	1.940
X_1	15	101.30	111.30	106.30	3.282	-0.051	1.729
X_2	15	25.30	27.80	26.59	0.804	-0.041	1.799

Source: Researcher's Computation (2022)

Table 43 presents the summary statistics of variables. For X_1 and X_2, the highest and lowest means are recorded respectively. The standard deviations for each variable indicate that there are lesser deviations. The results revealed that the predictor variables are negatively skewed. The coefficient of skewness is low, which means the data are fairly symmetrical. The variables exhibit low kurtosis and tend to have light tails. This means that there are less values in the tails than to a normal distribution, which further signified lack of outliers. Generally, the low values of kurtosis and skewness suggest that the variables' distribution are close to normality.

Table 44: **Correlation Matrix of Original Data**

Variables	X_1	X_2
X_1	1.000	
X_2	0.994	1.000

Source: Researcher's Computation (2022)

The correlation coefficient of -0.824 shows a very strong positive relationship between X_1 and X_2, and that the predictor variables can be considered very highly correlated. The very highly correlation between the variables indicates that multicollinearity might exist in the data. These are as presented in Table 44.

Table 45: **VIF and Durbin-Watson Test of Original Data**

VIF_1	VIF_2	dl	du	DW	p-value	α	ρ
79.26	79.26	0.946	1.543	0.382	0.000	0.05	0.77

Source: Researcher's Computation (2022)

Table 45 presents the VIF and Durbin-Watson tests of original data. The Durbin-Watson test was employed to check for autocorrelation and the VIF to check for multicollinearity. The DW value and the p-value are 0.382 and 0.000, respectively. Since $DW < dl$, the data suffer from positive first order autoregressive scheme and since the $VIF > 10$, the data also suffer from multicollinearity. Hence, the data suffers from both problems. We correct the autocorrelation problem by data transformation. We then obtained an estimate of ρ (0.77) and used the estimate of ρ to transform the original data.

Table 46: **Correlation Matrix of Transformed Data**

Variables	X_{1T}	X_{2T}
X_{1T}	1.000	
X_{2T}	0.999	1.000

Source: Researcher's Computation (2022)

Table 46 shows the correlation matrix after the transformation of the data. It can be seen that the transformed variables X_1T and X_2T are very highly positively correlated with each other with correlation coefficient of 0.999, and this suggesting that a linear relationship exists among them. Hence, a possible multicollinearity problem might still exist in the data.

Table 47: **VIF and Durbin-Watson Test of Transformed Data**

VIF_1	VIF_2	dl	du	DW	p-value	α
512.646	512.646	0.946	1.543	1.549	0.2385	0.05

Source: Researcher's Computation (2022)

The transformed data was diagnosed using the VIF and the Durbin-Watson (DW) tests. The DW statistic and the p-value are 1.549 and 0.2385, respectively. The results show that $DW > du$, therefore the data does not suffer from first order autoregressive scheme. This shows that the autocorrelation problem in the data is solved. But, since the value for VIF is greater than 10 $(VIF > 10)$, the model still suffers from multicollinearity. This is confirmed by the VIF and Durbin-Watson Test of transformed data in Table 47.

Table 48: **Statistical Outputs of Ordinary Least Square (OLS)**

Variable	Estimate	Std. Error	*t* value	*p*-value
Intercept	25.4341	1.3617	18.678	0.000
X_1	0.1343	0.1106	1.214	0.248
X_2	-0.1925	0.4517	-0.426	0.678
R-squared	0.8055			
Adj. R-squared	0.7730			
MSE	0.0233			
RMSE	0.1526			
F-statistic: *F* (2, 12)	24.84		*p*-value	0.00005

Source: Researcher's Computation (2022)

Table 48 presents the regression analysis of OLS method. The results indicate that the regression coefficients of the predictor variables were statistically insignificant at 5% level of significance. However, the *F*-statistic for the overall model is significant [*F* (2, 12) = 24.84, *p*-value = 0.00005]. This regression coefficients appearing to be insignificant and the overall model being significant may be due to multicollinearity among the predictors. The R-squared value of 0.8055 means the predictors can explain 80.55% of the variation in the response variable. The MSE of the OLS method is obtained as 0.0233.

Table 49: **Statistical Outputs of Ridge Regression (RR)**

Variable	Estimate	Std. Error	*z* value	*p*-value
Intercept	25.3717	1.3119	19.340	0.0000
X_1	0.1111	0.0610	1.823	0.0683
X_2	-0.0976	0.2458	-0.397	0.6913
R-squared	0.8047			
Adj. R-squared	0.7722			
MSE	0.0225			
RMSE	0.1501			
K	0.08697			

Source: Researcher's Computation (2022)

Table 49 presents the regression analysis of ridge regression (RR) method. The findings reveal that the regression coefficients of the predictors were found to be statistically insignificant at 5% level of significance. The findings of the analysis showed a decrease in standard error of the RR method in comparison to the OLS method. The R-square (0.8047) reveals that the predictor variables can explain 80.47% of the variation in the response variable. The MSE and RMSE values are 0.0225 and 0.1501 respectively, when the value of K = 0.08697.

Table 50: **Statistical Outputs of Lasso Regression**

Variable	Estimate	Std. Error	*z* value	*p*-value
Intercept	25.3138	1.2790	19.792	0.0000
X_1	0.0873	0.0120	7.247	0.0000
X_2	0.0000	0.0018	0.000	1.0000
R-squared	0.8025			
Adj. R-squared	0.7696			
MSE	0.0218			
RMSE	0.1478			
K	0.02848			

Source: Researcher's Computation (2022)

Table 50 presents the regression coefficients, R-squared value and estimated MSE of Lasso regression method. The regression analysis results conducted by using Lasso method revealed that the variable X_1 has a significant effect on the response variable according to *p*-value (0.0000) at 5% significance level. Moreover, the regression coefficient of X_2 is shrink to zero. The Lasso standard errors show a decrease compared to OLS method. The R-square (0.8025) shows that 80.25% variation in the response variable can be explained by the predictors. The MSE and RMSE values obtained by the Lasso method are 0.0218 and 0.1478 respectively, when the value of K is 0.02848.

Table 51: **Statistical Outputs of Two-Stage Ridge Regression (TR)**

Table 51 is the regression analysis results of two-stage ridge regression (TR). According to regression analysis results, regression coefficients of the X_1T and X_2T variables were found to be statistically insignificant at 5% significance level. This shows the predictor variables after the transformation of the data do not have much effect on the dependent variable. The R-square (0.9996) shows that 99.96% variation in the response variable can be explained by the predictors. The MSE and RMSE values computed are 0.0268 and 0.1637, respectively.

Table 52 is the regression analysis results of two-stage Lasso regression (TLasso). The results revealed that the predictor variables were found to be statistically insignificant at 5% significance level. The TLasso standard error is lower than that of the OLS method. The R-squared value (0.9998) shows that the predictor variables can explain 99.98% of the variation in the response variable. The MSE and RMSE values obtained by the TLasso method are 0.0148 and 0.1216, respectively.

Table 53 presents the coefficients of regression and MSE of methods. The regression coefficient of Lasso and TLasso seems to be much different from the other methods. Through comparison we found that the TLasso is the best as it has a high R-squared value (0.9998) and the smallest MSE value (0.0148) according to the interpretation of the data. Therefore, the TLasso method is most prefer method in fitting a linear model when assumptions of autocorrelation and multicollinearity are violated.

Table 54 presents the estimated regression coefficients and the mean squared error at the 0.25, 0.5 and 0.75 quantile levels for QR. The QR methods at various quantile levels have different coefficients sign. The coefficients having wrong signs might be due to the multicollinearity effect in the data. The QR method at quantile level 0.5 has the lowest MSE and the highest R-squared value. The R-square value of 0.6640 means the predictor variables can explain 66.40% of the variation in the response variable. The QR method at quantile level 0.5 is considered the best in this class of methods. However, this quantile level is weak in interpreting the data with the multicollinearity and autocorrelation problems.

Table 55 presents the comparison of performances of RQR and LQR at the quantile levels 0.25, 0.5 and 0.75. The LQR and RQR methods uses the L_1 and L_2-penalties respectively, in estimating the QR models. It can be seen that the RQR at quantile level 0.5 is the best as it has a high R-squared value of 0.6890 and the smallest MSE value of 0.0298. However, this quantile level is weak in interpreting the data with the multicollinearity and autocorrelation problems.

Table 56: **Comparison of TRQR and TLQR Methods**

Coefficient	TRQR			TLQR

Source: Researcher's Computation (2022)

Table 56 presents the comparison of the performances of two-stage ridge quantile regression (TRQR) and two-stage Lasso quantile regression (TLQR) at the quantile levels 0.25, 0.5 and 0.75. The MSE values (0.0078) and the R-square values (0.9999) of the TLQR at quantile level 0.25 and TLQR at quantile level 0.5 methods are obtained to be the same up to 4 decimal places, indicating the same performance. Therefore, both TLQR at quantile level 0.25 and TLQR at quantile level 0.5 are the most preferred method in fitting to the data, a linear regression model.

Table 57: **Comparison of TR, TLasso, TRQR and TLQR**

Source: Researcher's Computation (2022)

Table 57 presents the overall comparison of the performances of TR, TLasso, TRQR and TLQR methods. According to the R-squared values of the methods, TRQR and TLQR methods appear superior with respect to the variation the predictor variables can explain in the dependent variable. According to the MSE criterion of each regression method, the TLQR method at quantile level 0.25 and 0.5 have the smallest MSE value compared to the other methods. The results from comparisons of the methods revealed that both TLQR at quantile level 0.25 and TLQR at quantile level 0.5 are superior to the other methods. Therefore, the TLQR method is the best method in handling multicollinearity and autocorrelation problems in the dataset under study.

Discussion

The findings for two predictors revealed that with low autocorrelation and high degree of multicollinearity, TR method is superior to the other methods, especially with severe multicollinearity. However, the LQR and TLQR methods at quantile level 0.5 often competes favourably with the TR method. Increasing

the degree of multicollinearity provides an overall improvement in TR over the other regression methods for small predictor variables $(p = 2)$. We found that LQR method is either best or competes favourably with TLQR method when the degree of autocorrelation is very low with large sample size. Again, the comparisons of QR, RQR, LQR, TRQR and TLQR methods revealed that, both TRQR and TLQR methods at quantile level 0.5 perform better than the other methods. However, TRQR method produce better results than TLQR method in a model with small sample sizes. For sufficient high degrees of autocorrelation $(\rho = 0.9)$ with high multicollinearity, the TR method has the smallest MSE values and therefore outperforms the other methods for small predictors (p = 2). However, with large sample size (n = 500), the TLQR method at quantile level 0.5 is best.

The results for four predictor variables revealed that, TLQR method at 0.5 quantile level produce better results than the other methods in a model with severe multicollinearity $(\gamma^2 = 0.99)$ for the different samples size with very low degree of autocorrelation $(\rho = 0.1)$. However, some distinct patterns were identified. When n = 25 and n = 500 with sufficient high degree of autocorrelation $(\rho = 0.9)$, the TR method is best, and when $50 \leq n \leq 200$, the TLQR method at quantile level 0. 5 is generally best. Generally, comparison of the regularized and robust regression methods shows a general trend. Hence, both TR method and TLQR method at quantile level 0.5 are the best methods in handling multicollinearity and autocorrelation problems based on specific cases for four predictor variables.

The results for eight predictor variables in the presence of multicollinearity and autocorrelation revealed that, TR method outperforms the other methods.

But for severe multicollinearity level and many predictor variables, the TLasso method is superior and TR method is a close competitor. It has been revealed in this study that Lasso and TLasso methods performs better with many predictor variables ($p = 8$). For no or low degree of autocorrelation, the TLQR method at quantile level 0.5 has the least MSE values and therefore outperforms the other regression methods with small sample sizes ($25 \leq n \leq 50$). However, LQR method at quantile level 0.5 performs with large samples size ($200 \leq n \leq 500$) for eight predictor variables. The results indicated that the TLQR method at quantile level 0.5 outperforms the other methods when the autocorrelation is sufficiently high and across the different degrees of multicollinearity. However, for $25 \leq n \leq 50$ with high autocorrelation and severe multicollinearity, TR is best. Overall, we found that the TLQR method with an appropriate choice of quantile level is found suitable for addressing multicollinearity and autocorrelation problems with many predictor variables.

The study now looks at the use of the real data example to assess the performance of the methods. The study shown that the TLQR method still appears to be the best method in handling multicollinearity and autocorrelation problems in our real datasets. This research notes that the L_1-penalty added to the quantile regression loss function may have influence the performance of the TLQR method. Similarly, previous studies found that regularization (for instance, ridge and Lasso) in quantile regression has been proven to be effective in improving prediction accuracy (Bager, 2018; Li & Zhu, 2008; Li, Lin, & Xi, 2010; Suhail, Chand, & Kibria, 2020; Wu & Liu, 2009).

The results indicated that, when there is high degree of autocorrelation and multicollinearity level is also high, the OLS method has largest MSE with

inaccurate estimates of regression coefficients. These results confirm the works of Oyewole and Agunbiade (2020). They found that in the existence of multicollinearity and sufficiently strong autocorrelation, the OLS estimations of regression coefficients can be substantially erroneous (Oyewole & Agunbiade, 2020). If we take the MSE values as a criterion of comparison, we found that MSE values of TR is always less than the MSE values of RR. These findings are in line with the works of Hussein and Hytham (2021). They found that the TR method outperforms the RR, and that the regularization parameter values under the TR are always less than those under the RR.

Additionally, at no or low degree of autocorrelation and sufficiently low multicollinearity level with large sample size, the OLS estimate competes consistently with Lasso and TLasso methods. We found that the estimated MSE values of Lasso and TLasso methods decreases as the degree of multicollinearity increases with a smaller sample size. Therefore, the findings indicate that the sample size and number of predictor variables in the model are important in assessing the performances of the methods. According to Kristofer, Ghazi and Kibria (2010) MSE improves when the number of predictors is increased. They also found that when sample size increases, MSE lowers, even when the correlation between predictors is high. Additionally, the degree of autocorrelation and multicollinearity affects performances of regression methods. Zubair and Adenomon (2021) stated that, to avoid erroneous inferences when estimating regression model parameters, autocorrelation and multicollinearity between variables should be taken into account.

Chapter Summary

In this chapter, simulations of the regularized and robust regression methods were performed using two, four and eight predictor variables, 0.7, 0.9 and 0.99 multicollinearity levels, 0.1 and 0.9 degrees of autocorrelation, and samples of size 25, 50, 200 and 500 with 500 replications. Also, we compared the performances of the methods on two real data sets; the Portland cement data and the Historical data to determine which of the methods is the most effective in handling multicollinearity and autocorrelation problems in the datasets. The simulations and the real data analyses were performed using R software program.

The simulation results for two predictor variables show that the use of the TR method is generally effective in handling multicollinearity and autocorrelation problems for $25 \leq n \leq 200$. However, with large sample size (n = 500), the TLQR method at quantile level 0.5 was best. It was shown that, both TR method and TLQR method at quantile level 0.5 are the best methods in handling multicollinearity and autocorrelation problems in a dataset for four predictor variables. The simulation results for eight predictor variables revealed that the TLQR method at quantile level 0.5 outperforms the other methods when the autocorrelation is high and across the different degrees of multicollinearity with large sample size. However, for $25 \leq n \leq 50$ with high autocorrelation and severe multicollinearity, TR was best.

The real data was first explored to see the nature and spread of the data, and were further diagnosed using the variance inflation factor (VIF) and the Durbin-Watson (DW) tests to determine whether there is the presence of autocorrelation and/or multicollinearity in the datasets. The Portland cement data revealed the

existence of multicollinearity and the Historical data revealed the presence of both multicollinearity and autocorrelation. The study reveals that the TLQR method at quantile level 0.5 appears to be a suitable alternative in addressing the multicollinearity problem in the Portland cement dataset and also best in handling multicollinearity and autocorrelation problems in the Historical dataset.

CHAPTER FIVE

SUMMARY, CONCLUSIONS AND RECOMMENDATIONS

Overview

This chapter gives an overview of the various chapters and the conclusions that are drawn from the findings of the study. Based on the conclusions, relevant recommendations are provided.

Summary

The Ordinary Least Squares (OLS) possesses a very desirable property of being the Best Linear Unbiased Estimator (BLUE) when assumptions hold true. However, the OLS estimates can have extremely large mean squared error when there is multicollinearity. When the multicollinearity level gets higher, OLS estimates become imprecise, the model may have insignificant test, wider confidence interval, less interpretable are the parameters and the property of OLS being the BLUE does not hold anymore. Also, if the errors are correlated, then OLS can underestimate the standard error of the coefficients. When this happens, OLS estimate predictions will be inefficient. The literature reveals that the OLS estimates performance is unsatisfactory when autocorrelation and multicollinearity are present.

The topic under study seeks to examine different regularized and robust regression methods for handling multicollinearity and autocorrelation problems. Firstly, the performance of RR, Lasso, TR and TLasso methods were compared. Secondly, the performance of QR, RQR, LQR, TRQR and TLQR were also compared. Both real and simulated data are used in the study. Two real data sets were obtained for the purpose. Data was also simulated with three multicollinearity levels (0.7, 0.9 and 0.99), two degrees of autocorrelation (0.1

and 0.9), four different sample sizes (25, 50, 200 and 500) and three different number of predictor variables (2, 4 and 8). The simulation was replicated 500 times to obtain the approximate distribution. The R software program was used for the data analysis at various stages of the study. The regression methods applied for the analyses are OLS, RR, Lasso, TR, TLasso, QR, RQR, LQR, TRQR and TLQR. The study used three quantile levels (0.25, 0.5 and 0.75). The performances of these methods are compared to determine which method best addresses the problems of multicollinearity and autocorrelation.

The literature reveals a number of methods for addressing multicollinearity and autocorrelation problems, namely: generalized two stage ridge regression, feasible generalized restricted ridge regression, two-stage ridge regression, two-stage principal component regression, two-stage Liu regression, two-stage partial least square and two-stage $K-L$ method. The regularized and robust regression methods were reviewed thoroughly and their performance compared to arrive at the results of the study. These results are however different from what is in literature since it did not consider two-stage ridge quantile regression (TRQR) and two-stage Lasso quantile regression (TLQR) methods in handling multicollinearity and autocorrelation problems.

The study first presented the results from the simulated data for two predictor variables. The results from comparisons of OLS, RR, Lasso, TR and TLasso methods reveal that the TR method is superior to the other methods for both $\rho = 0.1$ and $\rho = 0.9$. Again, the comparisons of QR, RQR, LQR, TRQR and TLQR methods revealed that, both TRQR and TLQR methods at quantile level 0.5 showed superiority over the other methods. However, TRQR produce better outcomes than TLQR with small sample sizes. We compared the performances

of all the methods, and the results showed that, TR is best when multicollinearity is high with high autocorrelation for $25 \leq n \leq 200$. Moreover, with large sample size (n = 500), the TLQR method at quantile level 0.5 is best. The study further revealed that the estimated MSEs for TR is always less than that of RR when the multicollinearity and autocorrelation problems exist in a dataset. Overall, the use of the TR method for two predictor variables in a model is generally effective in handling multicollinearity and autocorrelation problems.

The simulation results for four predictor variables revealed that the TR method outperforms the OLS, RR, Lasso and TLasso methods for the samples size (25, 50, 200 and 500) and across the different degrees of multicollinearity (0.7, 0.9 and 0.99) for both $\rho = 0.1$ and $\rho = 0.9$. The results from comparisons of the methods show that, TLQR method at quantile level 0.5 is most preferred methods with very high multicollinearity level $(\gamma^2 = 0.99)$ at the different samples size (25, 50, 200 and 500) when $\rho = 0.1$. Moreover, TLQR method at quantile level 0.5 also performs better than the other methods (QR, RQR, LQR and TRQR) when $\rho = 0.9$. From the study findings, the TLQR method at 0.5 quantile level produce better results in a model with severe multicollinearity $(\gamma^2 = 0.99)$ for the different samples size when $\rho = 0.1$ than the other methods. When n = 25 and 500 with high autocorrelation $(\rho = 0.9)$, the TR method is best. However, when $50 \leq n \leq 200$, the TLQR method at quantile level 0.5 is generally best. Hence, both TR method and TLQR method at quantile level 0.5 are the best methods in handling multicollinearity and autocorrelation problems based on specific cases for four predictor variables.

The results of the study from the simulated data for eight predictor variables revealed the following findings. The results from comparisons of OLS, RR,

Lasso, TR and TLasso methods revealed that the TR method outperforms the other methods with high degree of multicollinearity. However, it is observed that with many predictor variables and very high degree of multicollinearity $(\gamma^2 = 0.99)$, TLasso has appreciable smaller MSE values and performs best. The simulation results when $\rho = 0.1$ show that the TLQR method at quantile level 0.5 outperforms the other regression methods with decreasing small sample sizes $(25 \leq n \leq 50)$. However, LQR method at quantile level 0.5 performs better than the other regression methods with large samples size $(200 \leq n \leq 500)$. The simulation results when $\rho = 0.9$ show that TLQR method at quantile level 0.5 outperforms the other methods (QR, RQR, LQR and TRQR) for the various samples size (25, 50, 200 and 500) and across the various degrees of multicollinearity (0.7, 0.9 and 0.99). Comparing the performance of all the methods, we observed that TLQR method at quantile level 0.5 outperforms the other methods with high autocorrelation $(\rho = 0.9)$. However, TR performs best with high autocorrelation and severe multicollinearity for $25 \leq n \leq 50$. Also, when $\rho = 0.1$, LQR produce better results with large sample sizes $(200 \leq n \leq 500)$. Whiles, TLQR produce better results with small sample sizes $(25 \leq n \leq 50)$.

Finally, the real data were diagnosed using the VIF and the Durbin-Watson (DW) tests to determine if there is the presence of autocorrelation and/or multicollinearity in the datasets. The tests revealed the presence of multicollinearity in the Portland cement dataset, and the presence of multicollinearity and autocorrelation in the Historical dataset. The study revealed that the TLQR method at quantile level 0.5 appears to be a suitable alternative in addressing the multicollinearity problem in the Portland cement

dataset. Also, the TLQR method still appears to be the best method in handling multicollinearity and autocorrelation problems in the Historical dataset.

Conclusions

The study found that in the existence of multicollinearity and strong autocorrelation, OLS estimations of regression coefficients can be substantially incorrect. Also, the OLS estimates could not perform well with regard to their MSE in the existence of autocorrelation and multicollinearity. With low levels of multicollinearity and large sample size, the OLS estimate competes with the Lasso and TLasso methods while the TLasso method also competes with TR when multicollinearity degree is very high with many predictor variables. It is also found from the simulation results that the MSEs for TR method is always less than that of RR method when the multicollinearity and autocorrelation problems exist in a dataset. We also observed that the TRQR and TLQR methods showed a significant improvement over the method of only quantile regression.

Whatever autocorrelation and multicollinearity degrees, the TR method has lowest MSE compared with the other methods for few predictor variables. Furthermore, sample size has a significant impact on method performance at all levels of autocorrelation and multicollinearity. However, TLQR method appears to improve in performance with large sample size. The study found that both the TR method and the TLQR method with an appropriate quantile level choice are the best methods in handling multicollinearity and autocorrelation problems in a dataset with few predictor variables depending on the sample size.

In existence of multicollinearity and sufficiently high degrees of autocorrelation for many predictor variables, regardless of the sample size, the

TLQR method is seen to be the best. However, in the presence of multicollinearity with less or no autocorrelation, the LQR method has minimum MSE compared to TLQR method for a large sample size. Also, under high degrees of autocorrelation and severe multicollinearity level, TR method is either best or competes also with TLQR method when there is a small sample size. Overall, the TLQR method with 0.5 quantile level is found to be suitable for addressing multicollinearity and autocorrelation problems with many predictor variables.

Recommendations

In developing linear models, multicollinearity and autocorrelation degrees between predictors should be considered to avoid erroneous inferences when estimating regression parameters. From the study, it has been observed that, the size of the sample has a considerable impact on effectiveness of regression methods. To effectively build a good model, it would be prudent to choose the appropriate samples with corresponding right regression method for data studies which include possible multicollinearity and autocorrelation issues.

The study has suggested the best estimation method that gives the least mean squared error under simultaneous multicollinearity and autocorrelation conditions. The performance of TR method is consistent with small sample sizes; while TLQR method is consistent with large sample sizes. Therefore, the TR method can be a good method in addressing multicollinearity and autocorrelation problems in a dataset with few predictor variables. However, for many predictor variables, TLQR method with 0.5 quantile level is what is found to be suitable in handling multicollinearity and autocorrelation problems simultaneously in regression analysis.

Finally, we would recommend for further studies that the same regularized methods and other robust options can be looked at in the existence of multicollinearity, autocorrelation and outliers. Further studies could also be conducted on assessing the performance of the regularized and robust regression methods on linear models which suffers from multicollinearity and higher order autoregressive schemes, such as second-order autoregressive process AR (2).
